The typical presentation is a seronegative lower extremity peripheral arthritis, usually accompanied by enthesitis (dactylitis, Achilles tendinitis, and plantar fasciitis). Mucocutaneous features are common, especially keratoderma blennorrhagicum (Figure 113-2) and circinate balanitis. Extensive psoriasiform skin rashes can occur. The clinical overlap makes it difficult sometimes to distinguish HIV-associated reactive arthritis from psoriatic arthritis.¹⁰

Table 113-1 Rheumatic Diseases Associated with or Occurring in Patients with Human Immunodeficiency Virus (HIV) Infection

Unique to HIV Infection	Encountered in HIV-Infected Patients	Ameliorated by HIV Infection but Worsening or Reappearing with IRIS
Diffuse infiltrative lymphocytosis syndrome	HIV-associated reactive arthritis	Rheumatoid arthritis
HIV-associated arthritis	Polymyositis	Systemic lupus erythematosus
Zidovudine-associated myopathy	Psoriatic arthritis	
Painful articular syndrome	Polyarteritis nodosa	
	Giant cell arteritis	
	Hypersensitivity angitis	
	Granulomatosis with polyangiitis	
	Henoch-Schönlein purpura	
	Behçet's syndrome	
	Infectious arthritis (bacterial, fungal)	

IRIS, immune reconstitution inflammatory syndrome.

Table 113-2 Distribution of Various Rheumatic Diseases from Various Sites

Feature	Cincinnati, Ohio	Houston, Texas	Madrid, Spain
No. of patients	1100	4467	556
HIV-associated arthralgia	NA	0.7%	1.6%
Myalgia	0.7%	0.6%	4.5%
PsA/Reactive arthritis	0.5%	0.6%	0.5%
HIV-associated arthritis	0%	0.5%	0.4%
DILS/Sjögren's syndrome	NR	3%-4%	NR

DILS, diffuse infiltrative lymphocytosis syndrome; HIV, human immunodeficiency virus; NA, not applicable; NR, not reported; PsA, psoriatic arthritis.

Table 113-3 Contrasting Features of Human Immunodeficiency Virus (HIV)-Associated Arthritis and Reactive Arthritis

Feature	HIV-Associated Arthritis	HIV-Associated Reactive Arthritis
Joint involvement	Asymmetric oligoarthritis/polyarthritis	Asymmetric oligoarthritis/polyarthritis
Mucocutaneous involvement	Absent	Present
Enthesopathy	Absent	Frequent
Synovial fluid white blood cell count	500-2000/ μ L	2000-10,000/ μ L
Synovial fluid cultures	Negative	Negative
Microorganisms in synovial membranes	HIV virus (?)	Chlamydia*
HLA-B27 association	Absent	70%-90%†

*Shown in non-HIV-associated reactive arthritis. Reports of such infections in patients with HIV-associated reactive arthritis are lacking.

†In whites.

Urethritis occurs in similar frequency as in HIV-negative reactive arthritis. Axial involvement and uveitis seem to be less common but do occur. Longitudinal studies from Africa have described an aggressive course with a poor prognosis.^{11,12}

HLA-B27 is found in 80% to 90% of patients with HIV-associated reactive arthritis, at least among whites.¹⁰ Studies from Africa have found most patients to be HLA-B27 negative, however.^{6,9} Some studies suggest that the presence of HLA-B27 antigen may slow the progression to AIDS.^{11,12} In asymptomatic HIV-infected, HLA-B27-positive individuals, cytotoxic T lymphocyte response is dominated by recognition of a gag-encoded p24 protein epitope that is not seen in HIV-positive, HLA-B27-negative individuals.^{13,14} Other human leukocyte antigen (HLA) class I antigens that have been associated with a better outcome in HIV

infection have been implicated in psoriasis and psoriatic arthritis and include HLA-B13 and HLA-B17 (B57, B58).^{12,13} HLA-B*5703 was protective against HIV progression in a Zambian population but conferred susceptibility to spondyloarthritis.¹⁵

Treatment

Treatment is similar to that for HIV-negative patients with reactive arthritis. NSAIDs are the mainstay; in particular, indomethacin is recommended, not only for its efficacy, but also for its inhibition of HIV replication that has been observed in vitro, which seems to be unique to this NSAID.¹⁶ Patients frequently have an inadequate response to NSAIDs alone. Sulfasalazine has been shown to be effective in some studies at doses of 2 g/day, and one study suggested that it ameliorated HIV infection.^{17,18} Methotrexate was initially believed to be contraindicated because of its immunosuppressive effect, but with careful monitoring of HIV viral loads, CD4⁺ counts, and the patient's clinical status, more recent studies have suggested a place for methotrexate in the treatment of reactive arthritis and psoriatic arthritis occurring in HIV infection.¹⁹

Hydroxychloroquine has been reported to be efficacious not only in treating HIV-associated reactive arthritis, but also in reducing HIV replication in vitro and in reducing HIV viral loads in vivo.²⁰ Arthritis and the cutaneous lesions of HIV-associated reactive arthritis and psoriatic arthritis have been found to respond to etretinate (0.5 to 1 mg/kg/day),²¹ although because of the side effects of this drug, its use should be reserved for patients unresponsive to other treatments. Tumor necrosis factor blockers have been used,^{22,23} although these agents should be used with extreme caution and only in patients with CD4⁺ counts greater than 200/ μ L and HIV viral load less than 60,000 copies/mm³.^{24,25} One prospective study of eight HIV patients with spondyloarthritis or rheumatoid arthritis found tumor necrosis factor blockers effective and safe for up to 5 years when these precautions were followed at initiation of therapy.²⁵

Psoriasis and Psoriatic Arthritis

The extent of skin involvement with psoriasis can be extensive (Figure 113-3) in HIV-positive patients, especially in patients not on antiretroviral treatment. Of note, cutaneous T cell lymphoma can resemble psoriasis and should be considered in the differential diagnosis of psoriasis in HIV-positive individuals.²⁶ A report from Zambia found 27 of 28 African patients with psoriatic arthritis to be HIV positive.²⁷ The arthritis was predominantly polyarticular, lower limb, and progressive. Psoriasis was commonly an extensive guttate-plaque admixture and, in contrast to the articular disease, was nonremittive with the onset of AIDS.²⁸ Antiretroviral treatment has been shown to be effective in treating HIV-associated psoriasis and its associated arthritis.²⁹ Phototherapy may improve the skin rash but also may enhance viral replication, worsen HIV disease, and increase the risk of skin cancer. Other agents reported to be efficacious include cyclosporine (although renal function must be monitored carefully) and etretinate. Methotrexate also can be used, albeit with caution.¹⁹ Tumor necrosis factor blockers can be used in patients with refractory disease, and a

Figure 113-2 Keratoderma blennorrhagicum in a patient with reactive arthritis and human immunodeficiency virus infection.

Figure 113-3 Disseminated psoriasis vulgaris in a patient with human immunodeficiency virus–associated psoriasis.

number of patients have shown dramatic improvement in skin lesions and in arthritis,^{24,25} although with the usual precautions (see earlier) because frequent polymicrobial infections while on the drug resulted in its discontinuation in some patients.³⁰

Undifferentiated Spondyloarthritis

Symptoms of reactive arthritis or psoriatic arthritis such as enthesopathy (plantar fasciitis, Achilles tendinitis) are observed in patients who do not otherwise develop full-blown disease.³¹ Treatment is symptomatic (NSAIDs, intralesional corticosteroid injections), although sulfasalazine should be considered in patients with more extensive disease.

Avascular Necrosis of Bone

Most cases of osteonecrosis have occurred after the introduction of highly active antiretroviral therapy (HAART).³² Dyslipidemia associated with protease inhibitors has been implicated most frequently, although no controlled studies have been performed to establish whether antiretroviral drugs per se predispose to this.³³ Other contributing factors include alcohol abuse and use of corticosteroids, megestrol acetate, antiphospholipid antibodies,³⁴ and intravenous drug abuse,³⁵ as well as HIV itself. The most common presenting symptom of osteonecrosis is pain on weight bearing and activity. Some patients may be asymptomatic, and the diagnosis is made based on incidental findings in radiologic studies. Most patients tend to present when subchondral collapse already has occurred. Radiographs, computed tomography (CT), magnetic resonance imaging (MRI), and nuclear medicine studies have been used successfully to diagnose osteonecrosis, as in HIV-negative patients.

Hypertrophic Pulmonary Osteoarthropathy

Hypertrophic pulmonary osteoarthropathy affects bones, joints, and soft tissues and can develop in HIV-infected patients with *Pneumocystis jiroveci* pneumonia. It is characterized by severe pain in the lower extremity; digital clubbing; arthralgia; nonpitting edema; and periarticular soft tissue involvement of the ankles, knees, and elbows. The skin over the affected areas is glistening, edematous, and warm. Radiography reveals extensive periosteal reaction and subperiosteal proliferative changes in the long bones of the lower extremity. A bone scan shows increased uptake along the cortical surfaces. Treatment of *P. jiroveci* pneumonia usually alleviates this condition.³⁶

Osteopenia and Osteoporosis

Osteopenia and osteoporosis occur more than three times as commonly in HIV-infected patients regardless of antiretroviral treatment³⁷ and can result in pathologic fractures. One meta-analysis found 15% of HIV-positive patients to have osteoporosis, and 52% to have osteopenia.³⁸ Abnormal bone metabolism was attributed to the HIV infection itself by some authors.³⁸ Risk factors for the development of osteopenia include use of protease inhibitors, longer duration of HIV infection, high viral load, high lactate levels, low bicarbonate levels, increased alkaline phosphatase levels, and lower body weight before antiretroviral therapy.³⁹ Vitamin D deficiency is also common in HIV patients, with reported frequency of 47% for moderate to severe vitamin D deficiency in one cohort.⁴⁰ A retrospective review of 211 HIV-positive patients found vitamin D deficiency to be associated with concomitant hepatitis C infection, previous AIDS, and higher CD4⁺ counts.⁴¹ Clinicians should have a low threshold to screen for vitamin D deficiency and should provide adequate repletion as necessary. Bisphosphonates and, in patients with HIV wasting syndrome, testosterone, have been used to preserve bone density.⁴²

HIV-ASSOCIATED MUSCLE DISEASE

Muscle involvement in HIV infection varies from uncomplicated myalgias or asymptomatic creatine kinase elevation to severe, disabling, HIV-associated polymyositis or pyomyositis (Table 113-4). HIV seroconversion also can coincide with myoglobinuria and acute myalgia, suggesting that myotropism for HIV may be present early in the infection.

Myalgia and Fibromyalgia

One-third of HIV-positive outpatients report myalgias,⁴³ and 11% describe fibromyalgia.⁴⁴ Fibromyalgia is associated with longer disease duration and a history of depression. Treatment is similar to that for fibromyalgia in the non-HIV setting.

Noninflammatory Necrotizing Myopathy and HIV-Related Wasting Syndrome

Severe wasting from chronic infection, malignancy, malabsorption, and nutritional deficiency often accounts for

Table 113-4 Myopathies Associated with Human Immunodeficiency Virus (HIV) Infection

HIV-Associated Myopathies	Myopathies Secondary to Antiretrovirals	Others
HIV polymyositis Inclusion body myositis Nemaline myopathy Diffuse infiltrative lymphocytosis syndrome HIV wasting syndrome Vasculitic processes Myasthenia gravis and other myasthenic syndromes Chronic fatigue and fibromyalgia	Zidovudine myopathy Toxic mitochondrial myopathies related to other NRTIs HIV-associated lipodystrophy syndrome Immune reconstitution syndrome related to HAART	Opportunistic infections involving muscle (toxoplasmosis) Tumor infiltrations of skeletal muscle Rhabdomyolysis

HAART, highly active antiretroviral therapy; NRTIs, nucleoside reverse transcriptase inhibitors.

weakness and disability in patients with AIDS. This wasting leads to loss of lean body and muscle mass. Cachexia and muscle wasting associated with HIV constitute slim disease in Africa. A noninflammatory necrotizing myopathy of unclear pathogenesis has been described, accounting for 42% of patients diagnosed with myopathy.⁴⁵ Even in patients without significant wasting, muscle biopsy specimens have shown diffuse atrophy, mild neurogenic atrophy, or thick filament loss without conspicuous inflammation. Whether this condition is immune mediated, as some have suggested,⁴⁶ or whether it is due to metabolic or nutritional factors remains unclear. Corticosteroids have been reported to restore muscle strength and mass.⁴⁷

Nemaline Myopathy

Nemaline myopathy is a rare disorder that has been described in some HIV-positive patients, in addition to its occurrence as a congenital disorder. Nemaline myopathy represents a nonspecific myofibril alteration resulting from Z band disruption.⁴⁸ Muscle biopsy specimens disclose prominent, randomly distributed atrophic type 1 fibers with numerous intracytoplasmic rod bodies in the centers of the fibers, corresponding to nemaline rods at electron microscopy. Necrotic fibers and inflammatory infiltrates usually are not found. Some patients have been described to have associated monoclonal gammopathy.⁴⁹ Although no inflammation is noted, corticosteroids may be useful. In addition, two cases of successful treatment with intravenous immunoglobulin (IVIG) have been reported.⁵⁰

HIV-Associated Polymyositis

HIV-associated polymyositis most typically manifests early in the course of HIV infection and may be the presenting feature. In one large series of HIV-positive outpatients from a county clinic in Texas, the frequency was 2.2 per 1000.⁵¹ The pathogenesis of HIV-associated polymyositis is unclear—possibly stemming from direct viral invasion (leading to a cytopathic effect and subsequent muscle necrosis), as suggested in one pathologic study,⁵² or from an autoimmune response of the HIV host, as suggested by another study.⁵³

The most common manifestation is a subacute, progressive proximal muscle weakness occurring in the setting of an elevated creatine kinase. Myalgia is not a prominent presenting feature. Skin involvement is unusual, as is involvement of extraocular muscles and facial muscles. On the other hand, only a handful of cases of dermatomyositis

in HIV have been reported, usually in the setting of advanced immunodeficiency.⁵⁴

It has been suggested that creatine kinase levels may be less elevated or even normal in some HIV-associated polymyositis patients. One retrospective report from sub-Saharan Africa found that creatine kinase elevations were fourfold lower in those with HIV-associated polymyositis than in patients with polymyositis without HIV infection.⁵⁵

On MRI, T2-weighted studies with or without fat saturation show high signal intensity without rim enhancement, in contrast to pyomyositis, in which rim enhancement is seen.⁵⁶ MRI also is helpful in guiding muscle biopsy—the definitive diagnostic test. Electromyographic studies reveal myopathic motor unit potentials with early recruitment and full interference patterns and fibrillation potentials, positive sharp waves, and complex repetitive discharges indicative of an irritative process. Light microscopy of muscle biopsy specimens shows interstitial inflammatory infiltrates of variable intensity accompanied by degenerating and regenerating myofibrils, similar to those seen in polymyositis without HIV (Figure 113-4). Concomitant vasculitis rarely occurs. In specimens from HIV-positive and HIV-negative patients with myositis, the predominant cell populations were CD8⁺ T cells and macrophages invading or surrounding healthy muscle fibers that express major histocompatibility complex (MHC) class I antigens on their cell surfaces.⁵⁷ Endomysial infiltrates in specimens from HIV-positive patients differed from those of patients with polymyositis without HIV infection only by a significant reduction of CD4⁺ cells.⁵³

Figure 113-4 Muscle biopsy specimen from a patient with human immunodeficiency virus–associated polymyositis.

Treatment is similar to that provided for other inflammatory myopathies. Creatine kinase elevation and muscle weakness respond to moderate-dose glucocorticoids.⁵¹ Refractory cases may require immunosuppressive agents, such as methotrexate, azathioprine, or mycophenolate mofetil. Intravenous immunoglobulin has been used with some success. These agents should be used with caution, however, with careful monitoring of the patient's clinical status, CD4⁺ counts, and HIV mRNA levels.

Creatine kinase elevation is commonly encountered in outpatients with HIV infection, secondary to HIV per se, behaviors associated with higher risk for HIV infection (e.g., cocaine use), or HIV treatment.⁵¹ In most patients, these elevations are transient and are of little consequence, but they require careful follow-up for any sign of clinical deterioration before electrodiagnostic and biopsy studies are undertaken.

Inclusion Body Myositis

Inclusion body myositis has been recognized as a complication of HIV infection.⁵⁸ This condition is clinically, histologically, and immunologically identical to sporadic inclusion body myositis. Muscle biopsy specimens suggest two concurrently ongoing processes—an autoimmune process mediated by cytotoxic T cells and a degenerative process manifested by vacuolated muscle fibers and deposits of amyloid-related proteins. Of particular interest has been the finding of elevated mRNA levels and constitutive expression of Toll-like receptor 3, which is known to mediate inflammatory stimuli from pathogens and endogenous danger signals, and to link the innate and adaptive immune systems, in muscle fibers of patients with HIV-associated inclusion body myositis in close proximity with infiltrating mononuclear cells.⁵⁹ One review of four cases of HIV-associated inclusion body myositis found that involved CD8⁺ cells surrounding muscle fibers were virus-specific and may cross-react with antigens on the surface of muscle fibers, suggesting that HIV may trigger a viral-specific inflammatory response that can lead to inclusion body myositis.⁶⁰

Myopathy Associated with Treatment

A reversible toxic mitochondrial myopathy occurring in patients who received high doses of zidovudine has been described, which manifests as myalgias, muscle tenderness, and proximal muscle weakness mimicking HIV polymyositis.⁶¹ Reports have also described mitochondrial toxicity presenting as ptosis or ophthalmoplegia in HIV-positive patients on zidovudine and other nucleoside reverse transcriptase inhibitors (NRTIs) such as didanosine.^{62,63} Histologically, it is characterized by the presence of *ragged red fibers*, a term coined to designate atrophic ragged red fibers with marked myofibril alterations, including thick myofilament loss and cytoplasmic body formation,⁶⁴ and minimal inflammatory infiltrates. Symptoms tend to improve as the drug is discontinued, with creatine kinase levels returning to normal within 4 weeks of discontinuing the drug, and muscle strength returning within 8 weeks. In any HIV-infected patient presenting with an elevated creatine kinase, especially when symptoms of myalgia or muscle weakness

are present, zidovudine should be discontinued for 4 weeks and the patient re-evaluated before electromyography or muscle biopsies are undertaken.

Rhabdomyolysis

Rhabdomyolysis can occur at all stages of HIV infection and may be separated into three groups: (1) HIV-associated rhabdomyolysis, including rhabdomyolysis in primary HIV infection, recurrent rhabdomyolysis, and isolated rhabdomyolysis; (2) drug-induced rhabdomyolysis; and (3) rhabdomyolysis at the end stage of AIDS, associated or not with opportunistic infection of muscle. Drugs implicated in rhabdomyolysis in HIV patients include didanosine, lamivudine, trimethoprim-sulfamethoxazole, ritonavir, indinavir, and zalcitabine.^{65,66}

DIFFUSE INFILTRATIVE LYMPHOCYTOSIS SYNDROME

Diffuse infiltrative lymphocytosis syndrome (DILS), found exclusively in HIV-positive patients, is characterized by salivary gland enlargement and peripheral CD8⁺ lymphocytosis often accompanied by sicca symptoms and other extraglandular features. The prevalence of DILS is declining since the introduction of HAART.⁶⁷ Using parotid enlargement as a criterion, the prevalence in Houston, Texas, was 4% in the pre-HAART era, declining to 0.8% after the introduction of aggressive HIV therapy.^{67,68} In another study from Greece, using xerophthalmia and xerostomia as the defining criteria (and requiring confirmatory minor salivary gland biopsy specimen and technetium scintigraphy),⁶⁹ the prevalence of DILS was 7.8% and decreased dramatically after the introduction of HAART.

The primary immunogenetic association has been with HLA-DRB1 alleles expressing the ILEDE amino acid sequence in the third diversity region—usually HLA-DRB1*1102, DRB1*1301, and DRB1*1302.^{67,70} Delayed progression to AIDS in patients with DILS has been attributed to delay in the evolution of the HIV virus from the less aggressive M-tropic strain to the more rapidly replicating T-tropic strain by a more effective CD8⁺ lymphocyte response.⁷⁰ This response has been attributed in part to the finding of sequence homology of a six-residue epitope shared by HLA-DRB1 alleles associated with DILS with a V3 loop on M-tropic HIV strains. Studies of immunophenotypes of circulating and tissue-infiltrating lymphocytes and salivary gland T cell receptor sequence analysis suggested that DILS represents an MHC-restricted, antigen-driven, oligoclonal selection of CD8⁺, CD29[−] lymphocytes that express selective homing receptors and infiltrate the salivary glands, lungs, and other organs, where they are postulated to suppress HIV replication.⁷¹

Minor salivary gland biopsy specimens show a focal sialadenitis, similar to that observed in Sjögren's syndrome, although destruction of the salivary glands tends to be lessened (Figure 113-5). CD8⁺ lymphocytes constitute most of the inflammatory infiltrate,^{72,73} in contrast to that seen in primary (non-HIV-associated) Sjögren's syndrome. Lymphoepithelial cysts are seen frequently in the parotid glands of patients with DILS, leading to inspissated salivary secretions that may be painful.

Figure 113-5 Minor salivary gland biopsy specimen from a patient with diffuse infiltrative lymphocytosis syndrome. Note the relative preservation of the glandular architecture, even with significant interstitial inflammation.

The characteristic, if not defining, presentation of DILS consists of painless parotid enlargement, often massive (Figure 113-6). This enlargement is accompanied by sicca symptoms in more than 60% of patients. Although parotid and submandibular enlargement is nearly universal in this disorder, certain extraglandular features also are prominent (Table 113-5). DILS and Sjögren's syndrome share some similarities and differences (Table 113-6).

Diagnostic criteria have been proposed for DILS as follows:

Figure 113-6 Massive bilateral asymmetric salivary gland enlargement in a patient with diffuse infiltrative lymphocytosis syndrome. This was the presenting feature of human immunodeficiency virus infection in this patient. Computed tomography revealed this to be a solid mass. At follow-up 2 years after this photograph was taken, the gland had not changed in size.

*25% to 50%, but decreasing.

†Due to mechanical compression by inflamed parotid tissue.

‡Poor prognostic indicator.

1. HIV seropositive by enzyme-linked immunosorbent assay and Western blot analysis.
2. Bilateral salivary gland enlargement or xerostomia persisting for longer than 6 months.
3. Histologic confirmation of salivary or lacrimal gland lymphocytic infiltration in the absence of granulomatous or neoplastic enlargement.

Minor salivary gland biopsy specimens are usually positive (see Figure 113-5). Gallium-67 scintigraphy (Figure 113-7) of the salivary glands has been used when lip biopsy was not feasible or equivocal. Tc99m pertechnetate scanning offers little diagnostic help. Scintigraphy is used as a primary diagnostic aid in patients on protease inhibitors because minor salivary gland biopsy specimens are rarely positive in patients on these drugs. CT also has been used to determine the extent of glandular swelling and to evaluate parotid cysts and possible salivary glandular malignancy.

Patients with asymptomatic glandular swelling and mild, if any, sicca symptoms can be observed over time (Table 113-7). Antiretroviral treatment is effective in treating the glandular swelling and sicca symptoms associated with DILS

Table 113-6 Similarities and Differences between Diffuse Infiltrative Lymphocytosis Syndrome (DILS) and Sjögren's Syndrome

Feature	DILS	Sjögren's Syndrome
Parotid swelling	Ubiquitous	Uncommon
Sicca symptoms	Common	Very common
Extraglandular symptoms	Common	Uncommon
Autoantibodies (antinuclear antibodies, anti-Ro/La)	Rare	Common
HLA class II association	DRB1*1102, DRB1*1301, DRB1*1302	DRB1*0301, DQA1*0501, DQB1*0201

Figure 113-7 The “snowman” sign. Gallium-67 scintigraphy of the parotid glands of a patient with diffuse infiltrative lymphocytosis syndrome occurring in the setting of hemophilia.

and complications such as neuropathy.⁶⁷ We have found also that moderate doses of corticosteroids (30 to 40 mg/day of prednisone) are effective in treating the glandular swelling and sicca symptoms of DILS without adversely affecting the frequency of opportunistic infections, increasing the viral loads, or depressing the CD4⁺ counts, although the effect is transient. Lymphocytic interstitial pneumonitis may require higher doses of corticosteroids (60 mg/day of prednisone), sometimes for extended periods. Radiation therapy should be avoided. Cranial nerve VII palsy tends to respond poorly to any treatment. Combination antiretroviral therapy has been reported to be effective in resolving parotid epithelial cysts, although when refractory, the cysts can be managed by aspiration and instillation of 1 mL (40 mg) of either methylprednisolone or triamcinolone suspension into the cyst (Figure 113-8). Frequent recurrence may necessitate surgical excision.

VASCULITIS ASSOCIATED WITH HIV INFECTION

A wide spectrum of vasculitis has been described in patients with HIV infection.^{74,75} Fever, malaise, weakness, rash,

Figure 113-8 Aspiration of a parotid epithelial cyst in a patient with diffuse infiltrative lymphocytosis syndrome.

headaches, and neurologic symptoms are common in HIV-positive patients, and triggers of vasculitis range from specific infectious agents and drugs to idiopathic causes. Among infectious causes, cytomegalovirus and tuberculosis are probably the most common. Inflammatory vasculitides are less common rheumatologic diseases that occur in less than 1% of HIV patients.

One series found 34 (23%) of 148 “symptomatic” HIV-positive patients to have vasculitis.⁷⁶ Of these patients, 11 met American College of Rheumatology criteria for a distinct category of vasculitis, including hypersensitivity vasculitis in 6, polyarteritis nodosa in 4, and Henoch-Schönlein purpura in 1. Another series of 98 Chinese patients found that 20% had vasculitis, including 15 with Behçet’s-like disease, 2 cases of Henoch-Schönlein purpura, 2 cases of digital gangrene, and 1 case of central nervous system vasculitis.⁷⁷ Granulomatosis with polyangiitis (formerly Wegener’s granulomatosis) and pulmonary microscopic polyangiitis can occur in patients with high CD4⁺ counts and during immune reconstitution. Churg-Strauss vasculitis has also been described.⁷⁸ Behçet’s syndrome and relapsing polychondritis occur in HIV infection⁷⁹ and respond to HAART.⁸⁰ Rapidly progressive focal necrotizing vasculitis of the aorta and large arteries with aneurysm formation and rupture has been described in Africans with HIV infection.⁸¹ Giant cell arteritis likewise has been described in patients with HIV infection with aortic root dilation.⁸² Kawasaki disease has been reported in HIV-positive children and adults.⁸³ Cryoglobulinemic vasculitis with associated lymphocytic interstitial pneumonia occurs with and without hepatitis C co-infection.

Patients with isolated central nervous system angiitis usually present with organic brain syndromes and neurologic deficit.⁸⁴ In children and in one case report in an adult, HIV-associated cerebral aneurysmal arteriopathy was described as causing multiple fusiform aneurysms in the circle of Willis.⁸⁵ Central nervous system vasculitis may manifest as recurrent strokes. Although imaging studies (MRI, angiography) may be helpful, brain biopsy may be necessary to establish the diagnosis. Necrotizing granulomatous vasculitis not limited to the central nervous system has been reported in patients with low CD4⁺ counts that

respond to antiretroviral therapy.⁷⁴ More recently, a case report has described leukocytoclastic cerebral vasculitis treated with anti-CD25 antibody.⁸⁶

Diagnosis is based on a high degree of suspicion and on angiography and biopsy of specific organ beds. Similar to immunocompetent patients, perinuclear antineutrophil cytoplasmic antigen (pANCA) and cytoplasmic antineutrophil cytoplasmic antigen (cANCA) may be useful with granulomatosis with polyangiitis or microscopic polyangiitis. However, biopsy with cultures is important to rule out infectious mimics.

Corticosteroids are the mainstay of treatment for HIV-associated vasculitis, although cytotoxic agents such as cyclophosphamide, intravenous immunoglobulin, and plasmapheresis have been used in refractory cases. Painful neuropathy secondary to vasculitis responds well to high-dose glucocorticoids, in contrast to HIV-associated peripheral neuropathy.⁸⁷

PRIMARY PULMONARY HYPERTENSION

Pulmonary hypertension is a severe life-limiting disease that often affects younger patients. Patients with AIDS and primary pulmonary hypertension present with a higher degree of pulmonary hypertension than non-AIDS patients.^{88,89} The predominant histopathologic finding has been a plexogenic pulmonary arteriopathy, although thromboembolic changes also have been reported. One group found an association with HLA-DRB1*1301 and HLA-DRB1*1302 and with the linked allele HLA-DRB3*0301.⁹⁰

Symptoms include progressive shortness of breath, pedal edema, nonproductive cough, fatigue, syncope or near-syncope, and chest pain. Pulmonary function tests show mild restrictive patterns with variably reduced diffusing capacities. In a review of 131 cases of pulmonary hypertension associated with HIV infection, the interval between the diagnosis of HIV disease and the diagnosis of pulmonary hypertension was 33 months. The median length of time from diagnosis to death was 6 months.⁹¹ Responses to vasodilator agents—calcium channel blockers, sildenafil, intravenous and inhaled prostanoids, and endothelin antagonists—and to HAART vary, and some studies show improved mortality.⁹²

HIV-ASSOCIATED MUSCULOSKELETAL INFECTION

Pyomyositis

Pyomyositis is a primary infection of skeletal muscle that does not arise from contiguous infection; it is presumably hematogenous in origin and often is associated with abscess formation. Rarely seen in developed countries, infectious myositis nonetheless is an important complication of HIV infection in areas most endemic for HIV, such as Africa and India. It tends to occur in later stages of the infection, with CD4⁺ counts less than 200/μL. *Staphylococcus aureus* is the most common pathogen.⁹³ Other organisms that have been implicated include *Streptococcus pyogenes*, *Cryptococcus neoformans*, *Mycobacterium tuberculosis*, *Mycobacterium avium-intracellulare*, *Nocardia asteroides*, *Salmonella enteritidis*,

Escherichia coli, *Citrobacter freundii*, *Morganella morganii*, *Pseudomonas aeruginosa*, and group A streptococci.

The clinical course of pyomyositis can be roughly divided into three stages: invasive, suppurative, and late. The first stage, which typically lasts 1 to 3 weeks, is characterized by localized cramp-like pain and induration in conjunction with a low-grade fever. Large muscle groups, particularly those of the lower extremities, are most often affected. The degrees of pain and fever increase in the second stage, which is characterized further by the development of edema and pus in the affected muscle. Untreated, the disease progresses to the third stage; within 3 weeks of onset, sepsis and death can occur.⁹⁴ The mortality rate associated with pyomyositis has been estimated to range from 1% to 20%. Ultrasound and MRI with contrast enhancement are effective in localizing infection, although sometimes, tagged white blood cell scans may be needed. Oral and intravenous antibiotics in conjunction with surgical drainage are often required.

Bacterial Arthritis and Osteomyelitis

No data suggest that bacterial infection of bones or joints occurs more frequently in patients with HIV infection. *S. aureus* is the most common infectious agent encountered, but parenteral drug use and not HIV infection per se may account for this. Many other organisms have been reported to cause osteomyelitis in HIV-infected patients, including *Mycobacterium tuberculosis*, *Salmonella*, *Nocardia asteroides*, *Streptococcus pneumoniae*, *Neisseria gonorrhoeae*, cytomegalovirus, invasive *Aspergillus*, *Toxoplasma gondii*, *Torulopsis glabrata*, *Cryptococcus neoformans*, and *Coccidioides immitis*. Osteomyelitis is associated with mortality rates of greater than 20% in HIV-infected patients. The most frequently involved bones are the wrist, tibia, femoral heads, and thoracic cage, but other rare sites, such as the patella and the mandible, have been reported.

Musculoskeletal Tuberculosis

Musculoskeletal involvement, the fourth most common extrapulmonary manifestation of tuberculosis, is found in about 1% to 5% of patients with tuberculosis. It can mimic many skeletal diseases and can manifest in various locations. Less than 50% of reported patients with musculoskeletal tuberculosis have radiographic evidence of pulmonary tuberculosis. *M. tuberculosis* disseminates hematogenously after an acute or reactivated pulmonary infection. Usually, skeletal tuberculosis lesions in immunocompetent patients are solitary, but in AIDS patients, they may have a multicentric distribution in about 30% of cases.⁹⁵ The vertebrae are the most common site involved, mostly the lower thoracic or upper lumbar segments. The frequency of tuberculous spondylitis is 50% to 66%, peripheral arthritis 20% to 30%, osteomyelitis 10% to 20%, and tenosynovitis and bursitis about 1% to 3%. Treatment includes four-drug antitubercular therapy and often surgical intervention.

Atypical Mycobacterial Infection

Musculoskeletal infection caused by atypical mycobacterial species is unusual in immunocompetent individuals.⁹⁶

Atypical mycobacterial species most commonly implicated in causing septic arthritis or osteomyelitis in HIV include *M. avium-intracellulare* complex, *Mycobacterium kansasii*, *Mycobacterium haemophilum*, *Mycobacterium terrae*, and *Mycobacterium fortuitum*. *M. haemophilum* has been most frequently implicated in skeletal infection, accounting for more than half of cases, and *M. kansasii* is second, accounting for an additional 25%. These are systemic infections that have involved several joints or skeletal sites. Cutaneous lesions, such as nodules, ulcers, and draining sinus tracts, occur in approximately 50% of patients.⁹⁶ These infections tend to occur late in the course of HIV, usually when the CD4⁺ T lymphocyte count is less than 100/ μ L. *M. avium-intracellulare* complex osteomyelitis has also been associated with immune reconstitution inflammatory syndrome after initiation of HAART.⁹⁷ Along with standard antituberculosis therapy, clarithromycin is effective.⁹⁶

Bacillary Angiomatosis Osteomyelitis

Bacillary angiomatosis is a multisystem infectious disease caused by two closely related organisms—*Bartonella henselae* and *Bartonella quintana*—initially described in patients with AIDS by Stoler and colleagues in 1983.⁹⁸ It seems to be a disease unique to HIV-infected patients and to a lesser degree to other immunocompromised patients.¹

The name *bacillary angiomatosis* came from descriptions of vascular proliferation as seen on histologic examination of clinical specimens, and from the bacilli identified on Warthin-Starry silver stain. Bacterial infection results in a vascular proliferative response ensuing in lesions in the skin (resembling Kaposi's sarcoma), lymph nodes (adenitis), central nervous system (aseptic meningitis or intracranial masses), bone (osteomyelitis), and liver (peliosis hepatis). Osteomyelitis is found in about one-third of patients in association with skin disease. These lesions usually are characterized by extensive destruction of the cortical bone, periostitis, medullary invasion, and an overlying soft tissue mass that might resemble cellulitis. Complete remission of

bacillary angiomatosis after doxycycline or erythromycin therapy occurs, although bone lesions may need surgical drainage.

Fungal Infections

In addition to bacterial infection, patients with advanced HIV infection (CD4⁺ T lymphocyte count <100/ μ L) are at high risk for fungal musculoskeletal infections, particularly infections caused by *Candida albicans*⁹⁹ and *Sporothrix schenckii*.¹⁰⁰ *S. schenckii* can manifest with oligoarticular or even polyarticular involvement and tenosynovitis (Figure 113-9), and can be particularly difficult to eradicate, requiring long-term suppressive antifungal therapy. Various disseminated fungal infections, such as histoplasmosis, cryptococcosis, and blastomycosis, occur in HIV and often cause osteomyelitis.

Parasitic Infections

Muscle toxoplasmosis is found in profoundly immunodepressed patients, typically presenting with a painful subacute myopathy and concurrent multivisceral toxoplasmosis.¹⁰¹ *Toxoplasma* cysts are observed mainly in muscle fibers in muscle biopsy specimens, and identification of cysts as *Toxoplasma* may be easier when specific antibodies or electron microscopy is used. Muscle weakness such as in polymyositis can occur in muscle toxoplasmosis. Treatment is based on a combination of drugs acting synergistically against *T. gondii*, including pyrimethamine and sulfadiazine or trisulfapyrimidines.

RESPONSE OF OTHER RHEUMATIC DISEASES TO HIV INFECTION

Early reports suggested that rheumatoid arthritis went into remission in the face of HIV infection. Early reports likewise suggested that HIV infection might reduce the activity of

Figure 113-9 A, Third metacarpophalangeal synovitis and common extensor digitorum longus tendon sheath effusion at the dorsal surface of the wrist. B, Dissecting Baker's cyst in the same patient with disseminated *Sporothrix schenckii* infection (organism cultured from synovial fluid obtained from both sites).

systemic lupus erythematosus, particularly at times of low CD4⁺ T cell counts. With emergence of the immune reconstitution syndrome, most autoimmune diseases appear de novo or recur with institution of HAART and increased CD4⁺ counts.^{5,102}

HAART-RELATED IMMUNE RECONSTITUTION SYNDROME

Coverage of antiretroviral therapy has increased from 7% in 2003 to 20% in 2005. Immune reconstitution inflammatory syndrome (IRIS) is a paradoxical clinical deterioration that occurs in patients with HIV who receive HAART as a result of improvement in cellular immunity. It was initially described with recrudescence of infections, but now, auto-inflammatory and autoimmune phenomena are being described. A meta-analysis of more than 13,000 HIV patients starting HAART found that 13% developed IRIS.¹⁰³ The mean time of onset of IRIS from the time of HAART initiation is approximately 9 months.¹⁰²

Shelburne and co-workers¹⁰⁴ put forth four criteria required for the diagnosis of immune reconstitution inflammatory syndrome, as follows:

1. Patient has been diagnosed with AIDS.
2. Treatment with anti-HIV therapy results in increased CD4⁺ counts and decreased HIV viral load.
3. Infectious and inflammatory symptoms appear during therapy.
4. Symptoms cannot be explained by a new cause.

Improved understanding of the immunology of IRIS has helped elucidate how atypical, hyperaccentuated inflammatory host responses to pre-existing or coexisting infection can occur in HIV patients taking HAART. HIV infection causes a relentless decline in CD4⁺ memory and naïve cells, an increase in activated T cells in the peripheral blood, and thymic dysfunction. HAART can lead to sustained suppression of HIV and concomitant repopulation of T cell counts in a biphasic mode.¹⁰⁵ The first phase represents the release of predominantly memory CD4⁺ cells and lasts a few weeks to months. The second phase, from approximately 6 months on, represents the main phase of naïve T cell proliferation and is accompanied by changes in T helper cytokine production profiles.^{106,107} IRIS can occur during both phases of immune recovery, and different infections and autoimmune phenomena occur in phase 1 compared with phase 2.

Organ-specific autoimmune phenomena have been described more often than generalized systemic autoimmune disease and tend to occur later during reconstitution. These phenomena may be a manifestation of naïve T cell release as opposed to memory T cell reconstitution. Graves' thyroiditis occurring about 21 months after initiation of HAART has been described in about 17 cases.¹⁰⁸ Terminal ileitis, alopecia universalis, cerebral CD8⁺ lymphocytosis, and Guillain-Barré syndrome^{105,109} have been reported. Polymyositis,¹¹⁰ rheumatoid arthritis,¹⁰² systemic lupus erythematosus,¹¹¹ Kawasaki-like febrile illness,⁸³ autoimmune hepatitis, adult Still's disease, and sarcoidosis¹¹² newly developing after initiation of HAART also have been described. These conditions tend to occur earlier during reconstitution compared with organ-specific autoimmunity. In addition, IRIS has been reported in the setting of tumor

necrosis factor (TNF) blocker discontinuation, with cryptococcal pneumonia occurring in an HIV-positive patient after stopping adalimumab.¹¹³

If a diagnosis of IRIS is made, HAART is continued and most symptoms resolve with little or no therapy. If inflammatory symptoms involve areas where significant damage secondary to uncontrolled inflammation is likely to occur, such as in the central nervous system or eye, HAART should be stopped, and careful use of corticosteroids should be considered. IRIS is less likely to occur if the CD4⁺ count is greater than 200/ μ L when HAART is initiated. Other risk factors for IRIS include being HAART naïve and the presence of a high antigenic burden with opportunistic infection when HAART is begun.^{114,115} Continued systematic analysis is needed, however, and guidelines need to be established for defining the autoimmunity associated with immune reconstitution. The prognosis for most IRIS cases is favorable because a robust inflammatory response may predict an excellent response to HAART in terms of immune reconstitution and, perhaps, improved survival.

RHEUMATOLOGIC COMPLICATIONS OF HIV TREATMENT

The myopathy associated with nucleoside transcriptase inhibitors such as zidovudine and the osteonecrosis and parotid lipomatosis associated with the use of protease inhibitors have been discussed previously. In addition to these conditions, cases of adhesive capsulitis, Dupuytren's contracture, tenosynovitis, and temporomandibular joint dysfunction have been reported as a consequence of indinavir treatment.¹¹⁶

LABORATORY ABNORMALITIES ASSOCIATED WITH HIV INFECTION

Humoral immunologic abnormalities are frequent in patients with HIV but are rarely associated with severe clinical signs. The most common laboratory abnormality is polyclonal hyperglobulinemia, found in 45% of HIV-positive individuals.¹¹⁷ Rheumatoid factor and antinuclear antibodies, usually in low titer, have been described in 17% of patients with HIV infection in some series,¹¹⁷ although anti-dsDNA antibodies and hypocomplementemia are rare. IgG anticardiolipin antibodies are found in 95% of untreated patients with AIDS, particularly in patients with advanced disease, and overall in 20% to 30% of HIV-positive individuals.¹¹⁸ They are rarely associated with thrombotic events. cANCA and pANCA have been described in the serum of HIV-positive individuals, as have anti-glomerular basement membrane antibodies.¹¹⁹ Cryoglobulinemia is decreasing in this population since the introduction of HAART.¹²⁰ Indeed with HAART, many of these serologic abnormalities tend to decrease or resolve.

CONCLUSION

The impact of the global HIV pandemic continues to grow, and rheumatologists need to be aware of the wide spectrum of rheumatic diseases that occur in HIV-positive patients.

HAART has changed the natural history of HIV infection. It has modified the frequency and expression of some HIV-related clinical syndromes and has been associated directly (toxicity) and indirectly (immune reconstitution) with the development of new ones. With longer survival and newer refinements in treatment, the spectrum of rheumatic disease seen in HIV-positive patients is very much a moving target for rheumatologists and is likely to continue to evolve.

Viral Arthritis

STANLEY J. NAIDES

KEY POINTS

Acute-onset, symmetric polyarthritis can be caused by viral infection, especially when accompanied by rash.

Always take exposure, travel, occupation, and vaccination histories.

Parvovirus B19 is the most common viral arthritis in the United States.

In adults with parvovirus B19 infection, rash may be subtle or absent.

Rubella arthritis occurs in young adults. Rubella vaccination has reduced the overall incidence of rubella infection but has shifted the peak age to young adults.

Arthralgia, arthritis, or neuropathic pain may occur after rubella vaccination; these conditions are usually self-limited in duration.

Alphaviruses are mosquito-borne causes of arthritis and rash. Outbreaks occur in endemic areas associated with rising mosquito populations and should be considered in travelers entering the United States.

Hepatitis B virus infection presents as an arthritis-urticaria syndrome.

Hepatitis C virus infection causes cryoglobulinemia and vasculitis. Cryoglobulinemic vasculitis often presents as palpable purpura of the lower legs.

The history of risk behaviors associated with hepatitis C virus infection may be remote.

Viruses are candidate causative agents for various rheumatic diseases in part because arthralgia and arthritis are prominent features of certain viral infections. Understanding how viruses cause arthritis and the nature of virus–host cell interactions may suggest how viruses precipitate, establish, or maintain chronic inflammatory arthritis such as rheumatoid arthritis.

Viral effects in a given host may depend on host factors such as age, gender, genetic background, infection history, and immune response. The ability of a given virus to infect a host may also depend on the viral mode of host entry, tissue tropism, replication strategy, cytopathologic effects, ability to establish persistent infection, viral expression of host-like antigens, and ability to alter host antigens. Viral modification of the regulation of cellular gene expression may contribute to autoimmunity. Infected cells may die by classic cell necrosis, programmed cell death (apoptosis), or autophagy. Initiation of an immune response to virally encoded antigens on the cell surface may target that cell for destruction and alter cell-cell interactions. The antibody

response may generate immune complexes that are deposited locally at the site of viral infection or systemically in synovium. Alternatively, cells may survive, but their behavior may be altered by the expression of viral genes. Trans-activation of cellular genes by viral gene products may induce the cell cycle or cytokines that elicit or perpetuate an immune response targeting host cells. Molecular mimicry of host autoantigens by viral proteins may break immune tolerance. Viral components may elicit “danger signals” that trigger an immune response.^{1,2}

PARVOVIRUS B19

Human parvovirus B19 is a member of the family Parvoviridae, subfamily Parvovirinae, genus *Erythrovirus*. It consists of the small, single-stranded DNA viruses that autonomously replicate in erythroid precursors (hence the genus name). B19 has no envelope and is approximately 23 nm in diameter. Productive infection occurs in erythroid precursors; infection of nonerythroid tissues occurs but is restricted, which means that if assembly of virions occurs, it is inefficient, or that nonstructural but not capsid structural viral genes are expressed, preventing virion assembly. Parvoviruses are species specific and are not known to readily cross species barriers. The common canine parvovirus does not infect humans.

Epidemiology

B19 infection is common and occurs worldwide. B19 typically is transmitted by respiratory secretions but may also be transmitted via pooled blood products. Outbreaks commonly occur in late winter and spring, when close contact is most common, although epidemics may also occur in summer and fall. Most B19 infections, especially in children, remain asymptomatic or are diagnosed as nonspecific viral illnesses. Outbreaks tend to occur in 3- to 5-year cycles, representing the time required for a new cohort of susceptible children to enter school. Up to 60% of adults have serologic evidence of past B19 infection.^{3,4} Susceptible adults in occupations with multiple exposures to children, such as schoolteachers and pediatric nurses, are at greatest risk (up to 50%) of acquiring infection during outbreaks.^{4,5} Sporadic cases do occur during nonepidemic periods. The diagnosis should be entertained even in the absence of surveillance data suggesting an outbreak.

Pathogenesis

The onset of joint symptoms and rash is associated temporally with the appearance of serum anti-B19

immunoglobulin (Ig)M antibody, suggesting a role for circulating immune complexes during the acute phase of the illness.⁶ Although little evidence of circulating virus has been noted in patients who have chronic joint symptoms, B19 DNA may be found in the bone marrow and synovium of patients with chronic B19 arthropathy. Persistence in chronic B19 arthropathy may be facilitated by failure to develop IgG antibodies to the N-terminal region of the minor capsid protein VP1, known to encode neutralizing epitopes.⁶ The presence of antibody to the B19 nonstructural protein NS1 in some cases of chronic B19 arthropathy probably reflects the immune response to NS1 on the surface of B19 virions or NS1 spilled during cell death.⁷ NS1 protein itself, however, may play a pathogenic role in perpetuating chronic B19 arthropathy through its interaction with cellular genes.⁸ NS1 protein upregulates *in vitro* transcription from the interleukin (IL)-6 promoter and from human immunodeficiency virus (HIV) long terminal repeats in the presence of *tat* and an intact *tar* element.^{9,10} A high prevalence of B19 DNA and proteins in synovium from rheumatoid arthritis patients was reported in association with enhanced synovial production of IL-6 and tumor necrosis factor.⁸ These findings remain controversial.¹¹ B19 may induce apoptosis through NS1, which is known to be toxic to cells.^{12,13} Production of NS1 in nonpermissive synovio-cytes could theoretically induce autoimmunity by disrupting normal patterns of cell interactions and intercellular regulation.

Diagnosis

Clinical Features

The incubation period from B19 infection to symptom onset is 7 to 18 days. B19 causes transient aplastic crisis in the setting of chronic hemolytic anemia.⁶ In otherwise healthy children, B19 causes erythema infectiosum, or fifth disease, characterized by bright red “slapped cheeks” and a macular or maculopapular eruption on the torso and extremities. Up to 70% of infected children may be asymptomatic; others may have mild flu-like symptoms, including fever, headache, sore throat, cough, anorexia, vomiting, diarrhea, and arthralgia. In adults, the rash tends to be subtler, and the slapped-cheek rash is usually absent. Uncommon dermatologic manifestations include vesicular or hemorrhagic vesiculopustular eruptions, purpura with or without thrombocytopenia, Henoch-Schönlein purpura, and a “socks and gloves” acral erythema. B19 infection may be associated with paresthesias in the fingers and, rarely, with numbness of the toes. Progressive arm weakness has been associated with mild nerve conduction slowing and decreased motor and sensory potential amplitudes. B19 may cross the placenta to infect the fetus, which may develop hydrops fetalis on the basis of B19-induced anemia or viral cardiomyopathy. Less commonly, B19 may cause pancytopenia, isolated anemia, thrombocytopenia, leukopenia, myocarditis, neuropathy, or hepatitis.¹⁴ Reports suggest that B19 may be associated with vasculitis, including giant cell arteritis.^{15,16}

Patients with congenital or acquired immunodeficiencies, including prior chemotherapy or acquired immunodeficiency syndrome (AIDS) due to HIV infection, may

Table 114-1 Prevalence of Joint Symptoms in Fifth Disease by Age: Port Angeles, Washington, 1961-1962

Symptom	Prevalence (%) by Age		
	0-9 yr	10-19 yr	>20 yr
Pain	5.1	11.5	77.2
Swelling	2.8	5.3	59.6

Data from Ager EA, Chin TDY, Poland JD: Epidemic erythema infectiosum, *N Engl J Med* 275:1326, 1966.

develop persistent B19 infection with chronic or recurrent anemia, thrombocytopenia, or leukopenia. B19 infection is the leading cause of pure red cell aplasia in patients with AIDS.^{17,18}

In a study of an erythema infectiosum outbreak in Port Angeles, Washington, in which subjects were identified on the basis of rash, the incidence of arthralgia and joint swelling increased with age (Table 114-1).¹⁹ In adults, a severe flu-like illness consisting of fever, chills, malaise, and myalgias may precede or accompany sudden-onset, moderately severe, symmetric polyarthritides in a rheumatoid-like distribution. The arthritis is characterized by prominent involvement of the finger proximal interphalangeal, metacarpophalangeal, wrist, knee, and ankle joints. Within 24 to 48 hours of onset, all affected joints become involved. Axial skeleton involvement is uncommon. Joint symptoms are usually self-limited.

After the initial infection, objective joint swelling, heat, and erythema, when present, tend to resolve over several weeks. A minority of patients have prolonged symptoms that fall into one of two patterns. Approximately two-thirds have continuous morning stiffness and arthralgias with intermittent flares. The remaining patients are symptom free between flares. Chronic B19 arthropathy may last months to years. Pain remains a prominent feature during flares; patients commonly report morning stiffness. Approximately 12% of patients presenting with “early synovitis” have B19 infection; most are women.⁶

Laboratory Tests

Viremia lasts 5 to 6 days and is associated with an absence of reticulocytosis and, in otherwise normal individuals, a minimal decrease in the concentrations of hemoglobin, neutrophils, and lymphocytes. Flu-like symptoms may occur during viremia. An IgM antibody response follows the initial viremia in 4 to 6 days and is associated with clearing of viremia and cessation of nasal shedding of virus.

The antibody response is associated with the second phase of clinical illness, characterized by rash and joint symptoms. Onset of the anti-B19 IgG antibody response occurs almost concurrently with the IgM response. The two clinical phases of illness often overlap. Low to moderate titers of rheumatoid factor and anti-DNA, antilymphocyte, antinuclear, and antiphospholipid antibodies may be present initially.²⁰⁻²⁴

During viremia, immune electron microscopy may detect virions in serum. However, this method is not readily available to clinicians. B19 DNA may be detected during viremia. However, because adult patients usually present

after the onset of joint symptoms, the most useful diagnostic test is anti-B19 IgM serology. Radioimmunoassays and enzyme-linked immunosorbent assays have been used to detect B19 antigen and specific antibody to B19 capsid.^{6,25,26} The anti-B19 IgM antibody response is usually positive for 2 months after the acute illness and may wane shortly thereafter. In some patients, anti-B19 IgM may be detected for 6 months or longer. A positive anti-B19 IgG antibody test in the absence of anti-B19 IgM usually is not diagnostically helpful because of the high seroprevalence of anti-B19 IgG in the adult population. Reports of B19 DNA in normal synovium suggest that testing for B19 DNA in these tissues is of little clinical utility in the absence of anti-B19 IgM.²⁷

Differential Diagnosis

Many patients with B19 arthropathy meet the American Rheumatism Association criteria for a diagnosis of rheumatoid arthritis: morning stiffness lasting longer than an hour; symmetric involvement; involvement of at least three joints; and involvement of the finger proximal interphalangeal, metacarpophalangeal, and wrist joints. Rheumatoid factor may be present at low to moderate titers. Absence of both rheumatoid nodules and joint destruction differentiate B19 arthropathy from classic, erosive rheumatoid arthritis.

Occasionally, B19 infection may present with features of systemic lupus erythematosus (SLE). Whether this represents a clinical mimic or indicates that B19 plays a role in initiating or precipitating SLE in these patients remains to be determined.⁶

Rubella in adults may present with rash and symmetric polyarthralgia or polyarthritis that is clinically indistinguishable from B19 infection. A history of prenatal rubella testing, prior rubella vaccination, or rubella exposure may aid the clinician in choosing the appropriate diagnostic serologies.

Treatment and Outcome

No specific treatment or vaccine has been identified for B19 infection. Therefore, treatment is symptomatic and consists of nonsteroidal anti-inflammatory drugs. Intravenous immunoglobulin has been successful in the treatment of bone marrow suppression and B19 persistence in immunocompromised patients,¹⁸ but initial studies suggest that this is not applicable to patients with chronic arthropathy. Long-term prognosis is good. Although subjective arthralgias and morning stiffness may be prolonged, joint destruction is not a feature of chronic B19 arthropathy. The role of B19 as a cofactor in the development of classic erosive rheumatoid arthritis has not been confirmed.

TOGAVIRUSES

The family *Togaviridae* includes the *Rubivirus* and *Alphavirus* genera.

Rubella Virus

Rubella virus is the sole member of the genus *Rubivirus*. It consists of enveloped, single-stranded RNA viruses. The

rubella virion is spherical and measures 50 to 70 nm in diameter, with a 30-nm dense core. Envelope glycoproteins form 5- to 6-nm spike-like projections that contain hemagglutination activity.²⁸

Epidemiology

Transmission is by nasopharyngeal secretions, with a peak incidence in late winter and spring. Vaccination has reduced the incidence of rubella outbreaks and has shifted the demographic profile from children to college students and adults. The incubation period from infection to rash is 14 to 21 days. Viremia precedes rash by 6 to 7 days, peaks just before the onset of rash, and clears within 48 hours after the onset of rash. Nasopharyngeal shedding of virus is detectable from 7 days before the appearance of rash until 14 days afterward, but it is maximal from just before the rash until 5 to 6 days later.²⁹

Pathogenesis

Rubella virus can persistently infect synoviocytes and chondrocytes in vitro. An inadequate humoral immune response to specific rubella envelope glycoprotein epitopes may allow rubella virus to persistently infect synovium and lymphocytes in patients with chronic rubella arthritis. The onset of rash and arthritis is concurrent with antibody production, suggesting a role for antibody or immune complexes.²⁹ Concentrations of rubella antibody are higher in synovial fluid than in serum. Synovial lymphocytes from infected individuals spontaneously secrete rubella antibody in vitro, suggesting that an immune response to rubella infection occurs in the joint.³⁰

Diagnosis

Clinical Features. Asymptomatic infection occurs in children and adults. Low-grade fever, malaise, coryza, and prominent lymphadenopathy involving posterior cervical, postauricular, and occipital nodes may precede rash by 5 days. A morbilliform rash may initially appear on the face and then spread to the torso, upper extremities, and lower extremities over 2 to 3 days. The facial rash may coalesce and clear as the extremities become involved. In some cases, the rash is only a transient blush.

Joint symptoms commonly occur in women beginning 1 week before or 1 week after the appearance of the rash. Symmetric or migratory arthralgias are more common than synovitis. Morning stiffness is prominent. Joint symptoms usually resolve over a few days to 2 weeks. Proximal interphalangeal, metacarpophalangeal, wrist, elbow, ankle, and knee joints are most frequently affected. Periarthritis, tenosynovitis, and carpal tunnel syndrome may be seen. In some patients, symptoms may persist for months to years.^{31,32}

Live attenuated rubella vaccines have caused a high frequency of postvaccination myalgia, arthralgia, arthritis, and paresthesia—symptoms similar to those seen in natural infection—beginning 2 weeks after inoculation and lasting less than a week. However, in some patients, symptoms may persist for longer than a year. RA27/3, the vaccine strain in current use, may cause postvaccination joint symptoms in 15% or more of recipients.^{31,32}

Two rheumatologic syndromes may complicate natural infection or vaccination in children. In the catcher's crouch syndrome, a lumbar radiculoneuropathy causes popliteal fossa pain on arising in the morning. Exacerbation of the pain by knee extension encourages the assumption of a baseball catcher's crouch position. The pain gradually subsides through the day but recurs the next morning. In the arm syndrome, brachial neuropathy causes arm and hand pain and dysesthesias that are worse at night. Both syndromes may occur beginning 1 to 2 months after infection or vaccination, with the initial episode lasting up to 2 months. Episodes recur for up to 1 year but eventually resolve without long-term sequelae.³³

Laboratory Tests. Although rubella may be cultured from tissues and body fluids, including throat swabs, detecting antirubella IgM antibody usually establishes the diagnosis of acute rubella infection. Diagnosis by anti-IgG antibody seroconversion requires paired acute and convalescent sera. IgM and IgG are usually present at the onset of joint symptoms. IgM antibody levels peak 8 to 21 days after symptom onset and wane by 5 weeks. Antirubella IgG rises rapidly over a period of 1 to 3 weeks and is long lived. A single positive IgG serum sample or a set of untitered IgG-positive screens documents only immunity.²⁹

Differential Diagnosis. Rubella arthritis needs to be differentiated from other viral arthritides and from inflammatory arthritides, including rheumatoid arthritis. It may be confused with parvovirus B19 infection.

Treatment and Outcome

Nonsteroidal anti-inflammatory drugs are useful to control symptoms. Some investigators have suggested the use of low to moderate doses of steroids to control symptoms and viremia.³⁴ Long-term prognosis is good.

Alphaviruses

Members of the genus *Alphavirus* are enveloped, single-stranded RNA viruses transmitted by mosquitoes.³⁵ Several cause acute febrile arthropathy, and their names reflect local

appreciation of their clinical impact. For example, *chikungunya* means "that which twists or bends up" (Tanzania). The related *o'nyong-nyong* virus means "joint breaker" in the Acholi (Uganda) dialect. *Igbo-ora* is "the disease that breaks your wings."

Epidemiology

Chikungunya, o'nyong-nyong, and igbo-ora viruses form a serologically related group. Chikungunya virus was isolated during an epidemic of febrile arthritis in Tanzania between 1952 and 1953. Similar epidemics probably occurred in Africa, Asia, India, Indonesia, and possibly the southern United States as early as 1779.³⁵ Mosquitoes responsible for transmission to humans define its geographic distribution (Table 114-2). A feared consequence of global warming is spread of the geographic range of infected mosquitoes.³⁶⁻³⁹

Chikungunya fever occurs endemically and in epidemics.⁴⁰ Outbreaks have been described in the Indian Ocean islands, Malaysia, and Hong Kong.⁴¹⁻⁴⁴ An outbreak occurred in Italy in 2007. A large-scale outbreak of the serologically related o'nyong-nyong virus occurred in the Acholi province of northwestern Uganda in February 1959; this outbreak spread through Uganda and the surrounding region at a rate of 2 to 3 kilometers daily, affecting more than 2 million people within 2 years.⁴⁵ After the initial o'nyong-nyong epidemic, clinical disease was not detected again until it re-emerged in the Acholi region in 1996.⁴⁶ Despite the absence of outbreaks in the intervening years, serologic surveys have demonstrated that o'nyong-nyong virus is endemic.⁴⁷

Weber's line is a hypothetical demarcation separating the Australian and Asiatic geographic zones. Antibodies to chikungunya virus are found west of Weber's line, and Ross River virus antibodies are found only east of it. Ross River virus causes epidemics of fever and rash in Australia, New Zealand, and the western Pacific islands.⁴⁸ In the Fiji Islands from 1979 to 1980, Ross River virus caused febrile polyarthritis in more than 40,000 individuals.⁴⁹ In Australia, endemic cases and epidemics occur in tropical and

Table 114-2 Mosquito Vectors and Reservoirs of Alphaviruses

Virus	Mosquito	Reservoir	Region
Chikungunya virus	<i>Aedes</i> species <i>Mansonia africana</i>	Baboons, monkeys, <i>Scotophilus</i> bat species	Africa, Asia
O'nyong-nyong virus	<i>Anopheles funestus</i> <i>Anopheles gambiae</i>	Unknown	Africa

Mayaro virus	<i>Haemagogus janthinomys</i>	Marmosets	Bolivia, Brazil, Peru

temperate regions annually.⁵⁰ Most cases occur in Queensland and New South Wales territories, where high rainfall and subsequent increases in mosquito populations usually precede epidemic periods. Infection rates in Australia range from 0.2% to 3.5% per year. Male and female infection rates are similar, but a female predominance has been noted in presenting cases. Most infected adults are symptomatic; the case rate for children is lower. Barmah Forest virus, another alphavirus with an increasing incidence in Australia, may manifest in a fashion similar to Ross River virus.⁵¹⁻⁵⁶

Individuals involved in outdoor activities or occupations in forested areas in Sweden, Finland, and the neighboring Karelian isthmus of Russia are at greatest risk for infection with Sindbis virus; in those regions, it is known as Okelbo disease, Pogosta disease, and Karelian fever, respectively. Birds are the intermediate host.⁵⁷ It has also been reported in central Africa, Zimbabwe, South Africa, and Australia in sporadic cases or small outbreaks.³⁵

Mayaro virus, first recognized in Trinidad in 1954, is endemic in the tropical rain forests of Bolivia, Brazil, and Peru. Cases have been imported into the United States in individuals traveling from endemic areas.⁵⁸

Diagnosis

Clinical Features. Chikungunya fever presents with an explosive onset of high fever and severe arthralgia after a 1- to 12-day incubation period. The fever lasts 1 to 7 days. Typically, a macular or maculopapular, sometimes pruritic, rash on the torso, extremities, and occasionally the face, palms, and soles occurs on day 2 to 5 of illness as the patient defervesces. The rash may last 1 to 5 days and may recur with fever. Isolated petechiae and mucosal bleeding may occur. In some patients, involved skin desquamates.^{59,60} Chemosis is prominent. Headache, photophobia, retro-orbital pain, pharyngitis, anorexia, nausea, vomiting, and abdominal pain may be present. Diffuse myalgia and back and shoulder pain are common. Migratory polyarthralgia, stiffness, and swelling affect predominantly the small joints of the hands, wrists, feet, and ankles. Large joints are less severely affected. Previously injured joints may be disproportionately affected. Large effusions are uncommon. Symptoms in children tend to be milder. Low-titer rheumatoid factor may be found in those with long-standing symptoms.

O'nyong-nyong fever is clinically similar to chikungunya fever.^{61,62} In 1984, igbo-ora caused an epidemic of fever, myalgias, arthralgias, and rash in four Ivory Coast villages. Sequencing of isolates from the 1996 outbreak of o'nyong-nyong fever suggested that igbo-ora virus is a variant of o'nyong-nyong virus.⁴⁶

Ross River virus polyarthralgia is severe, incapacitating, and often migratory and asymmetric.⁶³ Symptoms follow a 7- to 11-day incubation period. Finger interphalangeal and metacarpophalangeal joints, wrists, knees, ankles, shoulders, elbows, and toes are often involved. Polyarticular swelling and tenosynovitis are common. Arthralgias are worse in the morning and after inactivity. Rash is macular, papular, or maculopapular and may be pruritic. Vesicles, papules, or petechiae are typically seen on the trunk and extremities. The palms, soles, and face may be involved. Rash typically appears 1 to 2 days before joint symptoms,

but it may occur anywhere from 11 days before to 15 days after the onset of arthralgias, and it resolves by fading to a brownish discoloration or by desquamation. Half of patients have no fever, and those who do may have only modest fever lasting 1 to 3 days. Nausea, headache, and myalgia are common. Respiratory symptoms, mild photophobia, and lymphadenopathy may occur. Up to a third of patients have paresthesias and palm or sole pain. Carpal tunnel syndrome may be seen. Arthritis is less common and less prominent in Barmah Forest virus infection than in Ross River virus infection, but the rash is more common and florid.^{64,65}

Rash and arthralgia are the presenting symptoms in Sindbis virus infection, although one may precede the other by a few days. Constitutional symptoms are usually mild and include low-grade fever, headache, fatigue, malaise, nausea, vomiting, pharyngitis, and paresthesias. A macular rash typically begins on the torso and then spreads to arms and legs, palms, soles, and occasionally the head. Macules evolve to form papules that tend to vesiculate. Vesiculation is prominent on pressure points, including the palms and soles. As the rash fades, a brownish discoloration is left. Vesicles on the palms and soles may become hemorrhagic. The rash may recur during convalescence.⁶⁶

A Mayaro virus outbreak in Belterra, Brazil, in 1988 was characterized by sudden onset of fever, headache, dizziness, chills, and arthralgias in the wrists, fingers, ankles, and toes. The clinical attack rate was 80%. Joint swelling, unilateral inguinal lymphadenopathy, and leukopenia may be present. A maculopapular rash on the trunk and extremities lasts about 3 days.⁶⁷

Laboratory Tests. The diagnosis of alphavirus infection requires laboratory confirmation. Any febrile patient residing in or returning from an endemic area should undergo a laboratory investigation. Chikungunya virus may be isolated from serum on days 2 through 4 of illness.⁶⁸ Neutralizing antibody, hemagglutination inhibition activity, and complement fixation tests may be used to detect antibodies. Chikungunya virus-specific IgM antibodies may be found for 6 months or longer.⁶⁹ O'nyong-nyong virus may be isolated by intracerebral injection into suckling mice, in which it produces alopecia, rash, and runting. Hemagglutination inhibition or complement fixation tests identify o'nyong-nyong virus.^{70,71} Because chikungunya and o'nyong-nyong viruses are closely related serologically, mouse antisera raised to chikungunya virus or o'nyong-nyong virus react equally well with o'nyong-nyong virus, but o'nyong-nyong antisera do not react well with chikungunya virus. Molecular detection methods have improved diagnostic specificity.⁷²⁻⁷⁵ Specific reverse transcriptase polymerase chain reaction-based assays have been developed for viral RNA detection.^{73,76}

In chikungunya fever, synovial fluid shows decreased viscosity, poor mucin clot, and 2000 to 5000 white blood cells/mm³. Ross River virus has been isolated only from antibody-negative sera. In Australian epidemics before 1979, patients were antibody positive at the time of presentation. In contrast, patients during the Pacific island epidemics of 1979 to 1980 remained viremic and seronegative for up to 1 week after the onset of symptoms. Synovial fluid cell counts range from 1500 to 13,800 cells/mm³, predominantly monocytes and vacuolated macrophages.⁷⁷ Barmah Forest virus infection is confirmed by rising titers of specific

IgG.⁶⁴ Diagnosis of Sindbis virus infection is confirmed by specific serology.

Pathogenesis

Little is known about the pathogenesis of chikungunya fever or arthritis. Involved skin shows erythrocyte extravasation from superficial capillaries and perivascular cuffing. The virus adsorbs to human platelets, causing aggregation, suggesting a mechanism for bleeding. Synovitis probably results from direct viral infection of synovium. In one patient with chronic arthropathy, the synovium appeared atrophic on arthroscopy and was histologically normal.⁷⁸ The mechanisms of o'nyong-nyong virus pathogenesis are unknown. However, the virus was isolated from peripheral blood mononuclear cells in a patient in Chad.⁷⁹

Ross River virus antigen may be detected early in monocytes and macrophages by immunofluorescence, but intact virus is not identifiable by electron microscopy or cell culture.⁸⁰ Erythematous and purpuric rashes show mild dermal perivascular mononuclear cell infiltrates, mostly T lymphocytes. Purpuric areas also show erythrocyte extravasation. Viral antigen may be detected in epithelial cells in erythematous and purpuric skin lesions and in perivascular zones in erythematous lesions.⁸¹

Sindbis virus has been isolated from a skin vesicle in the absence of viremia. Skin lesions show perivascular edema, hemorrhage, lymphocytic infiltrates, and areas of necrosis. Anti-Sindbis virus IgM may persist for years, raising the possibility that Sindbis virus arthritis is associated with viral persistence.⁸²

Treatment and Outcome

Management is supportive. Nonsteroidal anti-inflammatory agents are useful, but aspirin should be avoided in view of the tendency for alphavirus rashes to develop a hemorrhagic component. Chloroquine has been used in chikungunya fever when nonsteroidal anti-inflammatory agents failed.⁸³ During the acute attack, range-of-motion exercises may decrease stiffness. In general, management of alphavirus infection is symptomatic; patients recover without sequelae. After acute chikungunya fever, symptoms may persist for months before resolution. Approximately 10% of patients still have joint symptoms 1 year after infection.⁷⁸ A few patients may develop chronic arthralgia. Case reports suggest that a few patients with chronic arthropathy develop destructive joint lesions, but a second process cannot be ruled out.

For persons with Ross River virus arthritis, mild exercise tends to improve joint symptoms. Half of all patients are able to resume their daily activities within 4 weeks, although residual polyarthralgia may be present. Joint symptoms may recur.⁸⁴ Arthralgia, myalgia, and lethargy may continue for at least 6 months in up to half of patients.⁶⁴ Relapsing episodes gradually resolve, but joint symptoms have been reported in a few patients for up to 3 years.^{63,85}

Nonerosive chronic arthropathy is common after Sindbis virus infection, with up to one-third of patients having arthropathy 2 years or longer after onset. A smaller number have symptoms for as long as 5 to 6 years.⁸² Mayaro virus-infected patients have persistent arthralgias for months.

HEPATITIS B VIRUS

Hepatitis B virus (HBV), a member of the family *Hepadnaviridae*, genus *Orthohepadnavirus*, is an enveloped, double-stranded, icosahedral DNA virus measuring 42 nm in diameter.^{86,87}

Epidemiology

HBV occurs worldwide and is transmitted by parenteral and sexual routes. Prevalence is highest in Asia, the Middle East, and sub-Saharan Africa. In China, the prevalence is as high as 10%, compared with 0.01% in the United States. In endemic regions, infection occurs at an early age, frequently perinatally. Early HBV infection is usually asymptomatic. Rates of HBV carriage and specific antibody positivity decline with age. In the West, most infections are acquired during adulthood through sexual or needle exposure, leading to acute hepatitis. Of those with hepatitis, 5% to 10% develop persistent infection. In endemic regions, HBV is a common cause of chronic liver disease and a leading cause of hepatocellular carcinoma.⁸⁶

Clinical Features

The time from infection to clinical hepatitis is usually 45 to 120 days. A preicteric prodromal period lasts several days to a month and may be associated with fever, myalgia, malaise, anorexia, nausea, and vomiting. Joint involvement is usually sudden in onset and often severe, with symmetric and simultaneous involvement of several joints. Alternatively, arthritis may be migratory or additive.^{88,89} The joints of the hand and knee are most often affected, but wrists, ankles, elbows, shoulders, and other large joints may be involved as well. Fusiform swelling occurs in the small joints of the hand. Morning stiffness is common. Arthritis and urticaria may precede jaundice by days to weeks and may persist for several weeks, but they usually subside soon after the onset of clinical jaundice. Arthritis is usually limited to the preicteric prodrome. Those who develop chronic active hepatitis or chronic HBV viremia may have recurrent polyarthralgia or polyarthritis.⁹⁰ Polyarteritis nodosa may be associated with chronic hepatitis B viremia.⁹¹

Diagnosis

Urticaria in the presence of polyarthritis should suggest the possibility of HBV infection. Acute hepatitis may be asymptomatic, but elevated bilirubin and transaminases are usually present when arthritis appears. At the onset of arthritis, peak levels of serum hepatitis B surface antigen (HBsAg) are detectable. Virions, viral DNA, polymerase, and hepatitis B antigen may be detectable in serum. Anti-hepatitis B core antigen IgM antibodies indicate acute HBV infection rather than past or chronic infection.⁹²

Pathogenesis

Significant viremia occurs early in infection. Soluble immune complexes with circulating HBsAg form as anti-HBsAg antibodies are produced. An immune complex-mediated arthritis usually results, with immune complex

deposition in synovium. Immune complexes containing HBsAg, antibody, and complement components may be detected.

HEPATITIS C VIRUS

Hepatitis C virus (HCV), a member of the family Flaviviridae, is an enveloped, single-stranded, spherical RNA virus measuring 38 to 50 nm in diameter.^{93,94}

Epidemiology

HCV infection occurs worldwide. Like HBV infection, seroprevalence is higher in Africa and Asia, where it may cause one-fourth of acute and chronic hepatitis cases. In Japan, up to 50% of hepatitides may be caused by HCV.⁹⁵ In the United States, an estimated 2.7 million individuals are infected.^{96,97}

HCV is transmitted by the parenteral route. Sexual transmission may occur but is uncommon.⁹⁸ More than half of all cases of non-A, non-B hepatitis are attributable to HCV infection.⁹⁹ Multiple HCV genotypes and quasi-species are organized into six major groups. They differ in pathogenicity, severity of disease, and response to interferon.⁹⁹⁻¹⁰³

Clinical Features

Acute HCV infection is usually benign. Up to 80% of post-transfusion infections are anicteric and asymptomatic. Liver enzyme elevations, when present, are usually minimal. Normal transaminase levels do not exclude HCV infection. Community-acquired cases may present more symptomatically and with significant transaminase elevations. Acute fulminant HCV hepatitis is rare. Acute HCV infection may be accompanied by acute-onset polyarthritis in a rheumatoid distribution, including the small joints of the hand, wrists, shoulders, knees, and hips.¹⁰⁴

HCV is often associated with mixed (type II and III) cryoglobulinemia. Essential mixed cryoglobulinemia—a triad of arthritis, palpable purpura, and cryoglobulinemia—is associated with HCV infection in most cases. Cryoglobulinemia in HCV infection is also seen in the absence of arthritis and purpura.¹⁰⁵ Cryoglobulinemia may be associated with necrotizing vasculitis. The presence of anti-HCV antibodies in essential mixed cryoglobulinemia is associated with more severe cutaneous involvement, such as Raynaud's phenomena, purpura, livedo, distal ulcers, and gangrene.¹⁰⁶ HCV RNA may be found in 75% of cryoprecipitates from patients with essential mixed cryoglobulinemia and anti-HCV antibodies.¹⁰⁷

Diagnosis

Serologic tests use an array of antigens in an enzyme immunoassay. A recombinant antigen strip immunoblot assay is confirmatory.¹⁰⁸ Polymerase chain reaction–based diagnostics allow confirmation of HCV viremia, viral load, and genotype.^{100,101} A minority of patients may have HCV RNA detectable by polymerase chain reaction amplification methods in the absence of positive serologic findings.¹⁰⁸⁻¹¹³ Liver biopsy for staging of liver disease is usually indicated

in patients who have serum anti-HCV antibody or RNA, even in the setting of normal liver enzymes, because liver enzymes do not reflect liver histology. A number of algorithms based on blood measures of liver involvement have been proposed to aid in staging.¹¹⁴⁻¹¹⁸

Pathogenesis

HCV infection persists despite antibody response to viral epitopes. Increased CD4⁺CD25⁺ regulatory T lymphocytes may blunt the immune response to HCV.¹¹⁸ A high rate of mutation in the envelope protein is responsible for the emergence of neutralization-escape mutants and quasi-species.¹¹⁹ HCV may contain an IgG Fc binding region on its surface; humoral immune response to HCV would, by epitope spreading, also target bound immunoglobulin Fc structures.¹²⁰ Chronic HCV infection leads to cirrhosis, end-stage liver failure, and hepatocellular carcinoma after a period of up to 20 years, but the frequency of these sequelae is debated, and the mechanisms by which they occur are unknown.¹²¹

Treatment

Initially, interferon- α 2b was used to suppress viral titers and ameliorate HCV liver disease in about half of patients and may have benefited HCV-associated cryoglobulinemia.¹²² Relapse after completion of the initial course of therapy was common. The current use of pegylated interferons that increase drug half-life and decrease clearance, and the addition of ribavirin, have improved outcomes.¹²³ Controversy continues regarding whether interferon therapy precipitates autoimmune diseases such as autoimmune thyroiditis.^{124,125} Those with cryoglobulinemia who fail interferon therapy require immunosuppressive therapy when vasculitis is present.

HUMAN T-LYMPHOTROPIC VIRUS TYPE 1

Human T-lymphotropic virus type 1 (HTLV-1), a retrovirus, is endemic in southern Japan, where it has been associated with oligoarthritis and a nodular rash (Figure 114-1). Anti-HTLV serology is positive. Type C viral particles are found in skin nodules. Synovial tissue is infiltrated by leukemic T lymphocytes with lobulated nuclei.¹²⁶⁻¹²⁸

OTHER VIRUSES

Joint involvement occasionally occurs in numerous other commonly encountered viral syndromes. Children with varicella rarely develop brief monoarticular or pauciarticular arthritis.¹²⁹ Mumps in adults is occasionally associated with small or large joint synovitis preceding or following the onset of parotitis by up to 4 weeks. Mumps arthritis may last several weeks.¹³⁰ Infection with adenovirus and with coxsackieviruses A9, B2, B3, B4, and B6 has been associated with recurrent episodes of polyarthritis, pleuritis, myalgia, rash, pharyngitis, myocarditis, and leukocytosis.¹³¹ Epstein-Barr virus–induced mononucleosis is frequently accompanied by polyarthralgia, but monoarticular knee arthritis sometimes occurs. A few cases of polyarthritis, fever, and myalgia due to echovirus 9 infection have been reported.¹³²

Figure 114-1 Nodular synovitis associated with human T-lymphotropic virus type 1 infection. (From Yancey WB Jr, Dolson LH, Oblon D, et al: *HTLV-I-associated adult T-cell leukemia/lymphoma presenting with nodular synovial masses*, *Am J Med* 89:676, 1990.)

Arthritis associated with herpes simplex virus or cytomegalovirus infection is rare, but a severe cytomegalovirus polyarthritis has been described in several immunocompromised bone marrow transplant recipients.¹³³ *Herpes hominis* occasionally causes arthritis of the knee in wrestlers, a condition referred to as *herpes gladiatorum*.¹³⁴ Knee arthritis has been reported as a rare complication after vaccinia inoculation.¹³⁵

Poststreptococcal Arthritis and Rheumatic Fever

ALLAN GIBOFSKY • JOHN B. ZABRISKIE

KEY POINTS

Acute rheumatic fever (ARF) is a delayed, nonsuppurative sequel of a pharyngeal infection with group A streptococci. Although a dramatic decline in the severity and the mortality of the disease has been noted, reports have described its resurgence in the United States.

Adequate treatment of documented streptococcal pharyngitis markedly reduces the incidence of subsequent ARF. Appropriate antimicrobial prophylaxis prevents recurrence of disease in known patients with ARF.

The clinical presentation of ARF varies. The lack of a single pathognomonic feature led to the development of the revised Jones criteria, which should be used to establish a diagnosis.

The terms *migrating* and *migratory* are often used to describe the polyarthritis of ARF, but these designations do not signify that the inflammation disappears in one joint when it appears in another. Rather, the various localizations usually overlap in time, and the onset, as opposed to the full course of arthritis, “migrates” from joint to joint.

Many investigators have suggested that poststreptococcal migratory arthritis (in adults and children) in the absence of carditis might be an entity distinct from ARF. Although these features may be seen (admittedly rarely), migratory arthritis without evidence of other major Jones criteria but supported by two minor manifestations still should be considered ARF, especially in children.

Antibiotic prophylaxis with penicillin should be started immediately after resolution of the acute episode. The optimal regimen consists of oral penicillin VK, 250,000 U twice a day, or parenteral penicillin G, 1.2 million U intramuscularly every 4 weeks.

Acute rheumatic fever (ARF) is a delayed, nonsuppurative sequel of pharyngeal infection with group A streptococci. After the initial streptococcal pharyngitis, a latent period of 2 to 3 weeks occurs. The onset of disease usually is characterized by an acute febrile illness, which may manifest in one of three classic ways: (1) The patient may present with migratory arthritis predominantly involving the large joints of the body; (2) concomitant clinical and laboratory signs of carditis and valvulitis may be noted; or (3) involvement of the central nervous system may manifest as Sydenham's chorea. The clinical episodes are self-limiting, but damage to the valves may be chronic and progressive, resulting in cardiac decompensation and death.

Although a dramatic decline in severity and mortality of the disease has been observed since the turn of the 20th

century, reports in recent years have described its resurgence in the United States¹ and in many military installations throughout the world—a reminder that the disease remains a public health problem even in developed countries. In addition, the disease continues essentially unabated in many developing countries. Estimates suggest that 10 to 20 million new cases will be reported per year in countries where two-thirds of the world population lives. For all of these reasons, it is important to keep rheumatic fever in the differential diagnosis of acute febrile illnesses, as well as acute inflammatory arthritis, in both children and adults.

EPIDEMIOLOGY

The incidence of ARF began to decline long before the introduction of antibiotics into clinical practice, decreasing from 250 to 100 patients per 100,000 population from 1862 to 1962 in Denmark.² The introduction of antibiotics in 1950 rapidly accelerated this decline, until by 1980, the incidence ranged from 0.23 to 1.88 patients per 100,000, with disease occurring primarily in children and teenagers. A notable exception has been in the native Hawaiian and Maori populations (both of Polynesian ancestry), among whom the incidence continues to be 13.4 per 100,000 hospitalized children per year.³

Only a few M serotypes (types 5, 14, 18, and 24) have been identified with outbreaks of ARF, suggesting that certain strains of group A streptococci may be more “rheumatogenic” than others.⁴ In Trinidad, types 41 and 11 have been the most common strains isolated from the oropharynx of patients with ARF. In our own series, conducted over a 20-year period (Table 115-1), many different M serotypes were isolated, including six strains that could not be typed. Kaplan and colleagues⁵ isolated several M types from patients seen during an outbreak of ARF in Utah, and these strains were mucoid and nonmucoid in character. Whether or not certain strains are more “rheumatogenic” than others remains unresolved. What is true, however, is that a streptococcal strain capable of causing well-documented pharyngitis is generally capable of causing ARF, although some notable exceptions have been recorded.⁶

PATHOGENESIS

Although little evidence suggests the direct involvement of group A streptococci in the affected tissues of ARF patients, a large body of epidemiologic and immunologic evidence indirectly implicates group A streptococci in initiation of the disease process: (1) It is well known that outbreaks of ARF closely follow epidemics of streptococcal sore throat or scarlet fever⁶; (2) adequate treatment of documented

streptococcal pharyngitis markedly reduces the incidence of subsequent ARF⁷; (3) appropriate antimicrobial prophylaxis prevents recurrence of disease in known patients with ARF⁸; and (4) if one tests the sera of ARF patients for three anti-streptococcal antibodies (streptolysin O, hyaluronidase, and streptokinase), most ARF patients (whether or not they recall an antecedent streptococcal sore throat) are found to have elevated antibody titers to these antigens.⁹

A note of caution is necessary concerning documentation (clinical or microbiologic) of an antecedent streptococcal infection. The frequency of isolation of group A streptococci from the oropharynx is extremely low, even in populations with limited access to antibiotics. An age-related discrepancy in the clinical documentation of an antecedent sore throat has been noted. In older children and young adults, the recollection of a streptococcal sore throat approaches 70%; in younger children, this rate approaches only 20%.¹ It is important to have a high index of suspicion of ARF in children or young adults presenting with signs of arthritis or carditis or both, even in the absence of a clinically documented sore throat.

Another intriguing, and as yet unexplained, observation has been the invariable association of ARF only with streptococcal pharyngitis. Although many outbreaks of impetigo have occurred, ARF almost never occurs after infection with these strains. In Trinidad, where impetigo and ARF are common infections, the strains colonizing the skin are different from those associated with ARF, and this does not influence the incidence of ARF.¹⁰ The explanation for these observations remains obscure.

Group A streptococci fall into two main classes based on differences in the C-repeat regions of the M protein.¹¹ One class is associated with streptococcal pharyngeal infection, and the other (with some exceptions) is commonly associated with impetigo. The particular strain of streptococci may be crucial in initiating the disease process. The pharyngeal site of infection with its large repository of lymphoid tissue also may be important in initiation of the abnormal humoral response by host to antigens cross-reactive with target organs. Finally, although impetigo strains do colonize the pharynx, they do not seem to elicit as strong an immunologic response to the M protein moiety as do the pharyngeal strains.^{12,13} This may prove to be an important factor,

especially in light of known cross-reactions between various streptococcal structures and mammalian proteins.

GROUP A STREPTOCOCCI

Figure 115-1 shows a schematic cross-section of group A streptococci. The capsule is composed of equimolar concentrations of *N*-acetyl glucosamine and glucuronic acid and is structurally identical to hyaluronic acid of mammalian tissues.¹⁴ Although numerous attempts to produce antibodies to this capsule have been unsuccessful,^{15,16} Fillet and colleagues¹⁷ were able to show high antibody titers to hyaluronic acid using techniques designed to detect nonprecipitating antibodies in the sera of immunized animals. Similar antibodies have been noted in humans.¹⁸ Data establishing the importance of this capsule in human infection have been almost nonexistent, although Stollerman¹⁹ commented on the presence of a large mucoid capsule as one of the more important characteristics of certain “rheumatogenic” strains.

With respect to the M protein moiety, investigations by Lancefield and others spanning almost 70 years²⁰ have established that the M protein molecule (at least 80 distinct serologic types) is perhaps the most important virulence factor in group A streptococcal infection of humans. The protein is a helical, coiled-coil structure that bears a striking structural homology to the cardiac cytoskeletal proteins, tropomyosin and myosin, and to many other coiled-coil structures, including keratin, DNA, lamin, and vimentin. When the amino acid sequence of many M proteins was delineated, it was possible to localize specifically the cross-reactive areas of the molecules. Studies of Dale and Beachey²¹ showed that the segment of the M protein involved in the opsonic reaction cross-reacted with human sarcolemma antigens. Sargent and co-workers²² more precisely localized this cross-reaction to the M protein amino acid residues 164 through 197.

Evidence implicating these cross-reactions in the pathogenesis of ARF remains scant. Antibodies to myosin have

Figure 115-1 Schematic representation of various structures of group A streptococci. Note the wide variety of cross-reactions between antigens and mammalian tissues.

Figure 115-2 Photomicrographs of immunofluorescent staining of heart sections with rabbit serum immunized with group A streptococcal membranes (A) and human serum obtained from a patient with acute rheumatic fever (B). Note the identical sarcolemmal staining patterns of these sera.

been detected in the sera of ARF patients, but they also are present in a high percentage of the sera obtained from individuals who had a streptococcal infection but did not subsequently develop ARF.²³ The significance of this observation is unclear because myosin is an internal protein of cardiac muscle cells and is not easily exposed to M protein cross-reacting antibodies. The group-specific carbohydrate of the streptococcus is a polysaccharide chain consisting of repeating units of rhamnose capped by *N*-acetyl glucosamine molecules. The *N*-acetyl glucosamine is immunodominant and gives rise to the serologic group specificity of group A streptococci.²⁴

Goldstein and associates²⁵ first described the cross-reaction between group A carbohydrate and valvular glycoproteins, and this reactivity was related to the *N*-acetyl glucosamine moiety present in both structures. Goldstein and Caravano²⁶ noted that rheumatic fever (RF) sera reacted to the heart valve glycoprotein. Fillet (unpublished data) observed strong reactivity of RF sera with purified proteoglycan material. These cross-reactions could involve the sugar moiety present in the proteoglycan portion of the glycoprotein and the carbohydrate.

It generally has been assumed that group A anticarbohydrate antibodies do not play a role in phagocytosis of group A streptococci. Salvadori and co-workers²⁷ showed, however, that human sera containing high titers of anti-group A carbohydrate antibody promoted opsonization and phagocytosis of many different M protein-specific strains, and the opsonophagocytic antibodies were directed to the *N*-acetyl glucosamine moiety of the group A carbohydrate. The mucopeptide portion of the cell wall is the “backbone” of the organism and is quite rigid in structure. It is composed of repeating units of muramic acid and *N*-acetyl glucosamine, cross-linked by peptide bridges.²⁸ It is particularly difficult to degrade and induces a wide variety of lesions when injected into various species, including arthritis in rats²⁹ and myocardial granulomas in mice resembling (but not identical to) RF Aschoff lesions.³⁰

The relationship of cell wall mucopeptides to the pathogenesis of ARF remains obscure. Elevated levels of antimucopeptide antibody have been detected not only in the sera of patients with ARF, but also in the sera of patients with rheumatoid arthritis and juvenile rheumatoid arthritis³¹; however, its pathogenetic relationship to clinical disease has been difficult to establish. No evidence indicates that cell wall antigens are present in the Aschoff lesion or in the myocardial tissue obtained from patients with ARF. Perhaps the most significant cross-reactions lie in the streptococcal membrane structure. We have shown that immunization with membrane material³² elicited antibodies that were bound to heart sections in a pattern similar to that observed with acute RF sera (Figure 115-2).

Kingston and Glynn³³ were the first to show that animals immunized with streptococcal antigens developed antibodies in their sera that stained astrocytes. Husby and associates³⁴ showed that sera from ARF patients with chorea exhibited antibodies that were specific for caudate cells. Absorption of the sera with streptococcal membrane antigens eliminated reactivity with caudate cells. Numerous other cross-reactions between streptococcal membranes and other organs have been reported (e.g., renal basement membranes, basement membrane proteoglycans, skin [particularly keratin]). In the context of this chapter, space does not permit an exhaustive discussion of these cross-reactions, and the reader is referred to other studies^{35,36} for a more detailed discussion. Whether or not these cross-reactions (especially the cross-reactions seen with basement membranes and skin) play a role in the disease awaits further study.

GENETICS

The concept that ARF might be the result of a host genetic predisposition has intrigued investigators for more than a century.³⁷ It has been variously suggested that the disease gene is transmitted in an autosomal dominant fashion³⁸ or

in an autosomal recessive fashion with limited penetrance,³⁹ or that it is possibly related to the genes conferring blood group secretor status.⁴⁰ Renewed interest in the genetics of ARF occurred with recognition that gene products of the human major histocompatibility complex (MHC) were associated with certain clinical disease states. Using an alloserum from a multiparous donor, an increased frequency of a B cell alloantigen was reported in several genetically distinct and ethnically diverse populations of ARF patients and was not MHC related.⁴¹

More recently, a monoclonal antibody (D8/17) was prepared by immunizing mice with B cells from an ARF patient.⁴² A B cell antigen identified by this antibody was found to be expressed on increased numbers of B cells in 100% of rheumatic patients of diverse ethnic origins, and in only 10% of normal individuals. The antigen defined by this monoclonal antibody showed no association with or linkage to any of the known MHC haplotypes, and it did not seem to be related to B cell activation antigens. Studies with D8/17 have been expanded to a larger number of patients with RF (see Table 115-1) of diverse ethnic origins with essentially the same results. As discussed subsequently, the presence or absence of elevated levels of D8/17⁺ B cells in cases of questionable RF has been helpful in establishing or ruling out the diagnosis.

These studies contrast with other reports in which an increased frequency of HLA-DR4 and HLA-DR2 has been seen in white and black patients with rheumatic heart disease (RHD).⁴³ Other studies have implicated HLA-DR1 and HLA-DRW6 as susceptibility factors in South African black patients with RHD.⁴⁴ Guilherme and associates⁴⁵ have reported an increased frequency of HLA-DR7 and HLA-DW53 in RF patients in Brazil.

These seemingly conflicting results concerning HLA antigens and RF susceptibility prompt speculation that these reported associations might be of class II genes close to (or in linkage disequilibrium with), but not identical to, the putative RF susceptibility gene. Alternatively, and more likely, susceptibility to ARF is polygenic, and the D8/17 antigen might be associated with only one of the genes (i.e., genes of the MHC complex encoding for DR antigens) conferring susceptibility. Although the explanation remains to be determined, the presence of the D8/17 antigen does seem to identify a population at special risk of contracting ARF (Table 115-2).

ETIOLOGIC CONSIDERATIONS

Although a large body of immunologic and epidemiologic evidence has implicated group A streptococci in the induction of the disease process, the precise pathologic mechanisms involved remain obscure. At least three main theories have been proposed. The first theory is concerned with the question of whether persistence of the organism is important. Despite several controversial reports, no investigators have been able to show consistently and reproducibly live organisms in RF cardiac tissues or valves.⁴⁶

The second theory revolves around the question of whether deposition of toxic products is required. Although an attractive hypothesis, little or no experimental evidence has been obtained to support this concept. Halbert and colleagues⁴⁷ have suggested that streptolysin O (an

*Acute patients.

extracellular product of group A streptococci) is cardiotoxic and might be carried to the site by circulating complexes containing streptolysin O and antibody. Despite an intensive search for these products, no such complexes in situ have been identified, however.^{48,49} Renewed interest in these extracellular toxins has emerged more recently with the observation by Schlievert and co-workers⁵⁰ that certain streptococcal pyrogenic toxins (A and C) may act as superantigens. These antigens may stimulate large numbers of T cells through their unique bridging interaction with T cell receptors of specific V β types and class II MHC molecules. This interaction is distinct from conventional antigen presentation in the context of the MHC complex. When activated, these cells elaborate tumor necrosis factor, interferon- γ , and numerous interleukin moieties, contributing to the initiation of pathologic damage. It has been suggested⁵¹ that in certain disease states, such as rheumatoid arthritis, autoreactive cells of specific V β lineage may "home" to the target organ.

Although an attractive hypothesis, no data concerning the role of these superantigens in ARF have yet been forthcoming. Perhaps the best evidence to date favors a third theory of an abnormal host immune response (humoral and cellular) in a genetically susceptible individual to the streptococcal antigens cross-reactive with mammalian tissues. Evidence supporting this theory may be divided into three broad categories:

1. Employing a wide variety of methods, numerous investigators have documented the presence of heart-reactive antibodies in ARF sera. The prevalence of these antibodies has ranged from 33% to 85% in various series. Although these antibodies are seen in other individuals (notably individuals with uncomplicated streptococcal infections that do not progress to RF and patients with poststreptococcal glomerulonephritis), the titers are always lower than those seen in RF and decrease with time during the convalescent

Table 115-3 Heart-Reactive Antibody Titers in Sera of Patients with Acute Rheumatic Fever Compared with Uncomplicated Streptococcal Infections

Clinical Disorder	No. Patients	Serum Dilutions			Average ASO Titer

†Serum samples obtained during active disease.

APSGN, acute poststreptococcal glomerulonephritis; ASO, antistreptolysin O; ND, not determined.

period (Table 115-3). An important point in terms of diagnosis and prognosis has been the observation by Zabriskie and associates⁵² that these heart-reactive antibody titers decline over time. By the end of 3 years, these titers are essentially undetectable in patients who had only a single attack (Figure 115-3). This pattern is consistent with the well-known clinical observation that recurrences of RF most often occur within the first 2 to 3 years after the initial attack and become rarer 5 years after an initial episode.

As illustrated in Figure 115-4, this pattern of titers also has prognostic value. During the 2- to 5-year period after the initial attack, a patient's titers decreased to undetectable levels. With a known break in prophylaxis starting in year 6, at least two streptococcal infections occurred, as evidenced by an increase in antistreptolysin O (ASO) titers during that period. The concomitant increase in heart-reactive antibody titers was notable. The final infection was followed by a clinical recurrence of classic rheumatic carditis complete with isolation of the organism, elevated heart-reactive antibodies, and acute phase reactants 11 years after the initial attack.

- Sera from patients with ARF also contain increased levels of antibodies to myosin and tropomyosin compared with sera from patients with pharyngeal streptococcal infections that do not progress to ARF. These myosin affinity purified antibodies also cross-react

with M protein moieties, suggesting that this molecule could be the antigenic stimulus for the production of myosin antibodies in these sera.^{23,53}

- Finally, as indicated earlier, autoimmune antibodies are a prominent finding in chorea, another major clinical manifestation of ARF, and these antibodies are directed against the cells of the caudate nucleus. The titer of this antibody corresponds with clinical disease activity.³⁴ Although not autoimmune in nature, the presence of elevated levels of immune complexes in ARF has been well documented in the sera and in the joints of ARF patients.⁵⁴ Elevated levels of immune complexes, which may be as high as the levels seen in classic poststreptococcal glomerulonephritis, may be responsible for the immune complex vasculitis seen in ARF tissues and may provide the initial impetus for vascular damage, followed by the secondary penetration of autoreactive antibodies. Support for this concept is the close clinical similarity of RF arthritis to experimentally induced serum sickness in animals or the arthritis seen secondary to drug hypersensitivity.

Deposition of host immunoglobulin and complement also is seen in the cardiac tissues of ARF patients, suggesting autoimmune deposition of immunoglobulins in or near the Aschoff lesions. At a cellular level, ample evidence has been found for the presence of lymphocytes and macrophages at the site of pathologic damage in the heart in patients with ARF.⁵⁵ The cells are predominantly CD4⁺ helper lymphocytes during acute stages of the disease (4:1). The ratio of CD4⁺ to CD8⁺ lymphocytes (2:1) more closely approximates the normal ratio in chronic valvular specimens. Most of these cells express DR antigens. A potentially important finding has been the observation that macrophage-like fibroblasts present in the diseased valves express DR antigens⁵⁶ and might be the antigen-presenting cells for the CD4⁺ lymphocytes. Increased cellular reactivity to streptococcal antigens also has been noted in the peripheral blood mononuclear cell preparations of ARF patients compared with these cells isolated from nephritis patients.⁵⁷

This abnormal reactivity peaks at 6 months after the attack, but may persist for 2 years after the initial episode. The reactivity was specific only for the strains associated with ARF, suggesting an abnormal humoral and cellular response to streptococcal antigens unique to RF-associated streptococci. Support for the potential pathologic importance of these T cells is strengthened further by the observation that lymphocytes obtained from experimental animals

Figure 115-3 Serial heart-reactive antibody titers in 40 patients with documented acute rheumatic fever. Note the slow decline of these titers over the first 2 years after the initial episode and the absence of these antibodies 5 years after the initial attack.

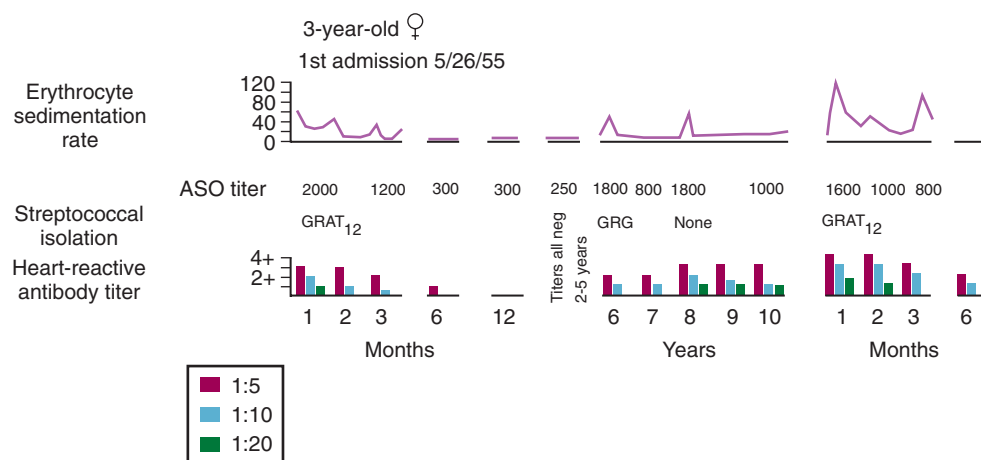

Figure 115-4 Heart-reactive antibody titers and laboratory data obtained from a patient with rheumatic fever who had two well-documented acute attacks 11 years apart. Note absence of the heart-reactive antibody during years 2 to 5 and its reappearance during years 6 to 10 after evidence of two intercurrent streptococcal infections secondary to breaks in penicillin prophylaxis (see antistreptolysin O [ASO] titers). High titers of heart-reactive antibody appeared with the second attack. CRP, C-reactive protein.

sensitized to cell membranes, but not to cell walls, are specifically cytotoxic for syngeneic embryonic cardiac myofibers in vitro.⁵⁸ In humans, normal mononuclear cells primed in vitro by M protein molecules from an RF-associated strain also are cytotoxic for myofibers, but specificity solely for cardiac cells was lacking in human studies.⁵⁹ Similar studies have not been performed yet using lymphocytes from active ARF patients (Table 115-4).

CLINICAL FEATURES

The clinical presentation of ARF varies, and the lack of a single pathognomonic feature has resulted in the

development of revised Jones criteria (Table 115-5),⁶⁰ which are used to establish a diagnosis. These criteria were established only as guidelines for the diagnosis and were never intended to be “etched in stone.” Depending on the age, geographic location, and ethnic population, emphasis on one criterion for the diagnosis of ARF may be more important than others. Manifestations of RF that are not clearly expressed pose a dilemma because of the importance of identifying a first rheumatic attack definitively to establish the need for prophylaxis of recurrences (see later). Some of the isolated manifestations, particularly polyarthritides, may be difficult or impossible to distinguish from other diseases, especially at their onset. The diagnosis can be made, however, when “pure” chorea is the sole manifestation

Table 115-4 Composition of Mononuclear Cellular Infiltrates in Acute and Chronic Active Rheumatic Valvulitis

Minor Manifestations
Arthralgia
Fever
Previous rheumatic fever or rheumatic heart disease
Supporting Evidence of Preceding Streptococcal Infection
Positive throat culture for group A beta-hemolytic streptococci
Increased antistreptolysin O or other streptococcal antibodies
Recent scarlet fever
Other Findings
Elevated acute phase reactants (C-reactive protein or erythrocyte sedimentation rate)
Prolonged P-R interval

*The diagnosis is made if the patient has two major criteria OR one major and two minor criteria if the history includes a preceding streptococcal infection.

Data from Jones criteria 1992 update: guidelines for diagnosis of rheumatic fever, *JAMA* 268:2069–2070, 1992.

because of the rarity with which this syndrome is due to any other cause. More recently, the World Health Organization updated the Jones criteria to allow for the diagnosis of recurrent ARF in patients with established RHD and chronic RHD (Table 115-6).

Table 115-6 Summary of 2002 World Health Organization Criteria for the Diagnosis of Rheumatic Fever (RF) and Rheumatic Heart Disease (RHD)

Diagnostic Categories	Criteria
Primary episode of RF	Two major or one major and two minor manifestations plus evidence of a preceding group A streptococcal infection
Recurrent attack of RF in patients without established RHD	Two major or one major and two minor manifestations plus evidence of a preceding group A streptococcal infection
Recurrent attack of RF in patients with established RHD	Two minor manifestations plus evidence of a preceding group A streptococcal infection
Rheumatic chorea, insidious onset of rheumatic carditis	One major manifestation or evidence of a preceding group A streptococcal infection
Chronic valve lesions of RHD (i.e., patients presenting for the first time with pure mitral stenosis, mixed mitral valve disease, and aortic valve disease)	No other criteria required for diagnosis of RHD

From *Rheumatic fever and rheumatic heart diseases: report of a WHO expert consultation*, WHO technical report series no. 923, Geneva, Switzerland, 2004, World Health Organization.

Arthritis

In classic, untreated cases, the arthritis of ARF affects several joints in quick succession, each for a short time. The legs usually are affected first, and the arms are affected later. The terms *migrating* and *migratory* are often used to describe the polyarthritis of ARF, but these designations are not meant to signify that the inflammation disappears in one joint when it appears in another. Rather, the various localizations usually overlap in time, and onset, as opposed to the full course of arthritis, “migrates” from joint to joint.

Joint involvement is more common, and also is more severe, in teenagers and young adults than in children. Arthritis is usually the earliest symptomatic manifestation of the disease, although asymptomatic carditis may precede it. Rheumatic polyarthritis may be excruciatingly painful but is almost always transient. The pain is usually more prominent than the objective signs of inflammation. When the disease is allowed to express itself fully, unmodified by anti-inflammatory treatment, more than half of patients studied show a true polyarthritis, with inflammation in 6 to 16 joints. Classically, each joint is maximally inflamed for only a few days, or a week at the most; the inflammation decreases, perhaps lingering for another week or so, and then disappears completely. Radiographs at this point may show a slight effusion but most likely are unremarkable.

In routine practice, many patients with arthritis or arthralgias are treated empirically with salicylates or other nonsteroidal anti-inflammatory drugs; arthritis subsides quickly in the joints already affected and does not migrate to new joints. Therapy may deprive the diagnostician of a useful sign. In a large series of patients with ARF and associated arthritis, most of whom had been treated, involvement of only a single large joint was common (25%). One or both knees were affected in 76%, and one or both ankles were affected in 50%. Elbows, wrists, hips, or small joints of the feet were involved in 12% to 15% of patients, and shoulders or small joints of the hand were affected in 7% to 8%. Rarely affected joints included the lumbosacral (2%), cervical (1%), sternoclavicular (0.5%), and temporomandibular (0.5%). Involvement of the small joints of the hands or feet alone occurred in only 1% of patients.⁶¹ Analysis of the synovial fluid in well-documented cases of ARF with arthritis generally reveals a sterile, inflammatory fluid. The complement components C1q, C3, and C4 may be decreased, indicating their consumption by immune complexes in the joint fluid.⁹

Poststreptococcal Reactive Arthritis

Numerous investigators⁶²⁻⁶⁴ have suggested that poststreptococcal migratory arthritis (in adults and children) in the absence of carditis might be a distinct entity from ARF for the following reasons: (1) The latent period between the antecedent streptococcal infection and the onset of poststreptococcal reactive arthritis is shorter (1 to 2 weeks) than the 3 to 4 weeks usually seen in classic ARF; (2) the response of the poststreptococcal reactive arthritis to aspirin and other nonsteroidal medications is poor compared with the dramatic response seen in classic ARF; (3) evidence of carditis is not usually seen in these patients, and the severity of the arthritis is marked; and (4) extra-articular

manifestations (e.g., tenosynovitis, renal abnormalities) are often seen in these patients.

Although these features may be seen (admittedly rarely), migratory arthritis without evidence of other major Jones criteria, if supported by two minor manifestations (see Table 115-5), still must be considered ARF, especially in children. Variations in the response to aspirin in these children often are not documented with serum salicylate levels, and an unusual clinical course is insufficient to exclude the diagnosis of ARF. Appropriate prophylactic measures should be taken.⁶⁵ Support for this concept may be found in the work of Crea and Mortimer.⁶⁶ In their series of patients with ARF, 50% of the children who presented solely with signs of migratory arthritis went on to develop significant valvular damage. RF also occurs in adults. Although migratory arthritis is a common presenting symptom, an outbreak in San Diego Naval Training Camp⁶⁷ revealed a 30% incidence of valvular damage in these patients. The importance of clearly defining this reactive arthritis as an RF variant has obvious implications for secondary prophylactic treatment. As suggested by some investigators, poststreptococcal reactive arthritis is a benign condition without the need for prophylaxis. Because most patients fulfill the Jones criteria (one major, two minor), they should be considered as having RF and, in our opinion, should be treated accordingly.

Carditis

Cardiac valvular and muscle damage can manifest in a variety of signs or symptoms. These manifestations include organic heart murmurs, cardiomegaly, congestive heart failure, and pericarditis. Mild to moderate chest discomfort, pleuritic chest pain, and a pericardial friction rub are indications of pericarditis. On clinical examination, the patient can have new or changing organic murmurs, most commonly mitral regurgitant murmurs and occasionally aortic regurgitant murmurs and systolic ejection murmurs, caused by acute valvular inflammation and deformity. Rarely, a Carey Coombs mid-diastolic murmur caused by rapid flow over the mitral valve is heard. If the valvular damage is severe, and concurrent cardiac dysfunction is present, congestive heart failure may occur. Congestive heart failure is the most life-threatening clinical syndrome of ARF and must be treated aggressively and early with a combination of anti-inflammatory drugs, diuretics, and, occasionally, steroids to decrease cardiac inflammation acutely.

Electrocardiogram abnormalities may include all degrees of heart block, including atrioventricular dissociation,

but first-degree heart block is not associated with a poor prognosis. Second-degree or third-degree heart block occasionally can be symptomatic. If heart block is associated with congestive heart failure, temporary pacemaker placement may be required. The most common manifestation of carditis is cardiomegaly, as seen on radiograph. Among patients at the Rockefeller University Hospital who were diagnosed with ARF between 1950 and 1970 with an average of 20 years of follow-up, 90% had evidence of carditis at diagnosis (Table 115-7). In Bland and Jones⁶⁸ classic review of 1000 patients with ARF, only 65% of patients were diagnosed with carditis. However, when Doppler sonography was employed in the clinical evaluation of patients during the Utah outbreak, 91% of patients had carditis,¹ indicating that, with more sensitive measurements of cardiac dysfunction, almost all ARF patients have signs of acute carditis.

Rheumatic Heart Disease

RHD is the most severe sequel of ARF. Usually occurring 10 to 20 years after the original attack, it is the major cause of acquired valvular disease in the world. The mitral valve is mainly involved, and aortic valve involvement occurs less often. Mitral stenosis is a classic RHD finding and can manifest as a combination of mitral insufficiency and stenosis, secondary to severe calcification of the mitral valve. When symptoms of left atrial enlargement are present, mitral valve replacement may become necessary.

In various studies, the incidence of RHD in patients with a history of ARF has varied. In Bland and Jones⁶⁷ classic follow-up study of patients with ARF, after 20 years, one-third of patients had no murmur, another one-third had died, and the remaining one-third were alive with RHD. Most of the patients who died had RHD. Although the classic dogma is that patients with RHD invariably have had more than one attack of ARF, analysis of our patients at the Rockefeller University Hospital disproves this notion. The population studied consisted of 87 patients who had only one documented attack of ARF with no evidence (clinical or laboratory) of recurrence during a 20-year follow-up under close supervision. More than 80% had carditis at admission, and approximately 50% now have organic murmurs (see Table 115-7). Valvular damage manifesting as organic murmurs later in life is still likely to occur in 50% of patients, particularly if they presented with evidence of carditis at initial diagnosis. All of the patients in our population who ended up with RHD had presented with carditis at diagnosis.

Table 115-7 Signs and Symptoms of Acute Rheumatic Fever: Rockefeller University Hospital, 1950 to 1970

	RHD (n = 40) (%)	No RHD (n = 47) (%)	Total (N = 87) (%)	Bland and Jones (%)
Carditis	100	83	90.1	65.3
Arthritis	67.5	68.1	67.8	41
Epistaxis	0	10.6	5.7	27.4
Chorea	5	2.1	3.4	51.8
Pericarditis	2.5	4.3	3.4	13
Subcutaneous nodules	7.5	0	3.4	8.8
Erythema marginatum	0	4.3	2.3	7.1

RHD, rheumatic heart disease.

Chorea

Sydenham's chorea (chorea minor, or St. Vitus' dance) is a neurologic disorder consisting of abrupt, purposeless, nonrhythmic involuntary movements, muscular weakness, and emotional disturbances. Involuntary movements disappear during sleep but may occur at rest and may interfere with voluntary activity. Initially, it may be possible to suppress these movements, which may affect all voluntary muscles, with the hands and face usually the most obviously affected. Grimaces and inappropriate smiles are common. Handwriting usually becomes clumsy and provides a convenient way of following the patient's course. Speech is often slurred.

Movements are commonly more marked on one side and occasionally are completely unilateral (hemichorea). Muscular weakness is best revealed by asking the patient to squeeze the examiner's hands: The pressure of the patient's grip increases and decreases continuously and capriciously—a phenomenon known as *relapsing grip*, or the *milking sign*. Emotional changes manifest as outbursts of inappropriate behavior, including crying and restlessness. In rare cases, psychological manifestations may be severe, possibly resulting in transient psychosis. The neurologic examination fails to reveal sensory losses or pyramidal tract involvement. Diffuse hypotonia may be present.

Chorea may follow streptococcal infection after a latent period, which is longer, on average, than the latent period of other rheumatic manifestations. Some patients with chorea have no other symptoms, but other patients develop chorea weeks or months after arthritis. In both cases, examination of the heart may reveal murmurs.

It has been known for years that the early symptoms of chorea often manifest as emotional or behavioral changes in the patient,⁶⁹ and only later do the choreiform motor symptoms appear. It also has been noted that many chorea patients years after choreiform symptoms had subsided would present with behavioral disorders, such as tics or obsessive-compulsive disorders. These earlier observations, combined with the known presence of antibrain antibodies in the sera of Sydenham's chorea patients, raised the question of whether a prior streptococcal infection (or infection with other microbes) might induce antibodies cross-reactive with brain antigen involved in neural pathways associated with behavior. Two more recent articles^{70,71} suggest a strong association of the D8/17 B cell marker (described earlier) with children with obsessive-compulsive disorder (see Table 115-6). Although Swedo and co-workers⁷⁰ selected patients on the basis of a strong history of prior streptococcal infection, Murphy and colleagues⁷¹ noted a strong association of the marker in patients with obsessive-compulsive disorder without a history of streptococcal infection. These preliminary studies suggest that streptococci and probably other microbes may induce antibodies that functionally disrupt the basal ganglia pathways, leading not only to classic chorea, but also to behavioral disorders without evidence of classic chorea.

Subcutaneous Nodules

The subcutaneous nodules of ARF are firm and painless. The overlying skin is not inflamed and usually can be moved

over the nodules. The diameter of these round lesions varies from a few millimeters to 1 or 2 cm. They are located over bony surfaces or prominences or near tendons. Their number varies from a single nodule to a few dozen and averages three or four; when numerous, they are usually symmetric. Nodules are rarely present for longer than 1 month. They are smaller and more short-lived than the nodules of rheumatoid arthritis. Although in both diseases, the elbows are most frequently involved, rheumatic nodules are more common on the olecranon, whereas nodules of rheumatoid arthritis are usually found 3 or 4 cm distal to it. Rheumatic subcutaneous nodules generally appear only after the first few weeks of illness, usually only in patients with carditis.

Erythema Marginatum

Erythema marginatum is an evanescent, nonpruritic skin rash, pink or faintly red, that affects usually the trunk and sometimes the proximal parts or the limbs, but not the face. This lesion extends centrifugally, while the skin in the center returns gradually to normal—hence the name *erythema marginatum*. The outer edge of the lesion is sharp, whereas the inner edge is diffuse. Because the margin of the lesion is usually continuous, making a ring, it is also termed *erythema annulare*. Individual lesions may appear and disappear in a matter of hours, usually to return. A hot bath or shower may make them more evident or may reveal them for the first time. Erythema marginatum usually occurs in the early phase of the disease. It often persists or recurs, even when all other manifestations of disease have disappeared. Occasionally, the lesions appear for the first time or, more likely, are noticed for the first time late in the course of the illness or even during convalescence. This disorder usually occurs only in patients with carditis.

Minor Manifestations

Fever

Temperature is increased in almost all ARF attacks and ranges from 38.4° C to 40° C. Usually, fever decreases in approximately 1 week without antipyretic treatment and may become low grade for another 1 or 2 weeks. Fever rarely lasts for longer than 3 to 4 weeks.

Abdominal Pain

The abdominal pain of RF resembles that of other conditions associated with acute microvascular mesenteric inflammation and is nonspecific. It usually occurs at or near the onset of the RF attack, so that other manifestations may not yet be present to clarify the diagnosis. In many cases, abdominal pain may mimic acute appendicitis.

Epistaxis

In the past, epistaxis occurred most prominently and severely in patients with severe and protracted rheumatic carditis. Early clinical studies reported a frequency of 48%, but it probably occurs even less frequently now (see Table 115-6). Although epistaxis has been correlated in the past

with the severity of rheumatic inflammation, it is difficult to assess retrospectively the possible thrombasthenic effect of large doses of salicylates, administered for prolonged periods in protracted attacks.

Rheumatic Pneumonia

Pneumonia may appear during the course of severe rheumatic carditis. This inflammatory process is difficult or impossible to distinguish from pulmonary edema or the alveolitis associated with respiratory distress syndromes owing to a variety of pathophysiologic states.

LABORATORY FINDINGS

The diagnosis of ARF cannot readily be established by laboratory tests. Nevertheless, such tests may be helpful in two ways: first, in showing that an antecedent streptococcal infection has occurred, and second, in documenting the presence or persistence of an inflammatory process. Serial chest radiographs may be helpful in following the course of carditis, and an electrocardiogram may reflect the inflammatory process on the conduction system. Throat cultures are usually negative by the time ARF appears, but an attempt should be made to isolate the organism. It is our practice to take three throat cultures during the first 24 hours, before administration of antibiotics. Streptococcal antibodies are more useful because (1) they reach a peak titer at about the time of onset of ARF; (2) they indicate true infection, rather than transient carriage; and (3) when several tests for different antibodies are performed, any significant recent streptococcal infection can be detected.

To show a rising titer, it is useful to take a serum specimen when the patient is first seen and to take another 2 weeks later for comparison. The specific antibody tests that have been used most frequently to diagnose streptococcal infection are those directed against extracellular products, including ASO, anti-DNAse B, antihyaluronidase (anti-diphosphopyridine nucleotide [anti-DNAse]), and anti-streptokinase. ASO has been the most widely used test and is generally available in U.S. hospitals. ASO titers vary with age, season, and geography. They reach peak levels in elementary school-aged children; titers of 200 to 300 Todd units/mL are common in healthy children. After streptococcal pharyngitis, the antibody response peaks at about 4 to 5 weeks, which is usually during the second or third week of ARF (depending on how early it is detected). Antibody titers decrease rapidly over the next several months, and after 6 months, they decline more slowly.

Because only 80% of cases of documented ARF exhibit an increase in the ASO titer, it is recommended that other antistreptococcal antibody tests be done in the absence of a positive ASO titer. These include anti-DNAse B, antihyaluronidase, and anti-streptozyme (a combination of various streptococcal antigens). Streptococcal antibodies, when increased, support but do not prove the diagnosis of ARF, and they are not a measure of rheumatic activity. Even in the absence of intercurrent streptococcal infection, titers decline during the rheumatic attack despite the persistence or severity of rheumatic activity.

Acute Phase Reactants

Acute phase reactants are elevated during ARF, just as they are during other inflammatory conditions. C-reactive protein and erythrocyte sedimentation rates are almost invariably elevated during the active rheumatic process, if they are not suppressed by antirheumatic drugs. These values may be normal, however, during episodes of pure chorea or persistent erythema marginatum. Particularly when treatment has been discontinued or is being tapered off, C-reactive protein and erythrocyte sedimentation rates are useful in monitoring “rebounds” of rheumatic inflammation, which indicate that the rheumatic process is still active. If C-reactive protein or erythrocyte sedimentation rate remains normal a few weeks after antirheumatic therapy is discontinued, the attack may be considered ended unless chorea appears. Usually, no exacerbation of systemic inflammation occurs, and chorea is present as an isolated manifestation.

Anemia

A mild, normochromic, normocytic anemia of chronic infection or inflammation may be seen during ARF. Suppressing the inflammation usually improves the anemia; hematinic therapy usually is not indicated.

Other Supporting Findings

As noted in Figures 115-3 and 115-4 and Table 115-2, two other tests have been helpful in our experience in confirming the diagnosis of ARF, especially when the diagnosis is in doubt. First, one can detect elevated titers of heart-reactive antibodies directed against sarcolemmal antigens in most ARF patients. Elevated levels of these antibodies are not seen in uncomplicated streptococcal infection or acute poststreptococcal glomerulonephritis. With the use of enzyme-linked immunosorbent assay, antibodies directed against cytoskeletal constituents such as myosin and tropomyosin also are seen to be elevated in ARF patients; this observation might be helpful in determining whether or not cross-reactive antibodies unique to ARF exist.⁵¹ Second, use of the D8/17 monoclonal antibody mentioned earlier also has proved helpful in the differential diagnosis of ARF from other disorders. In our hands, all RF patients express abnormal levels of D8/17⁺ B cells, especially during the acute attack. In cases in which the diagnosis of ARF has been doubtful, the presence of elevated levels of D8/17⁺ B cells has proved very helpful in establishing the correct diagnosis.⁴¹

CLINICAL COURSE AND TREATMENT

The mainstay of treatment for ARF has always been anti-inflammatory agents, most commonly aspirin. Dramatic improvement in symptoms usually is seen after initiation of therapy. Usually, 80 to 100 mg/kg/day in children and 4 to 8 g/day in adults is required for an effect to be seen. Aspirin levels can be measured; 20 to 30 mg/dL is the therapeutic range. Duration of anti-inflammatory therapy can vary, but treatment needs to be maintained until all symptoms are

absent and laboratory values are normal. If severe carditis also is present (as indicated by significant cardiomegaly, congestive heart failure, or third-degree heart block), steroid therapy can be instituted. The usual dosage is 2 mg/kg/day of oral prednisone during the first 1 to 2 weeks. Depending on clinical and laboratory improvement, the dosage is tapered over the next 2 weeks, and during the last week, aspirin may be added in the above recommended dose, sufficient to achieve 20 to 30 mg/dL.

As noted by Cillers⁷² in a clinical review, studies have shown no difference in the risk of cardiac disease at 1 year in groups treated with aspirin or corticosteroids. Similarly, although nonsteroidal anti-inflammatory drugs also have been used to treat acute inflammation, none have been the subject of randomized controlled trials. Whether or not signs of pharyngitis are present at the time of diagnosis, antibiotic therapy with penicillin should be started and maintained for at least 10 days, given in doses recommended for the eradication of streptococcal pharyngitis. Additionally, all family contacts should be cultured and treated for streptococcal infection if positive. If compliance is an issue, depot penicillins (i.e., benzathine penicillin G, 600,000 U in children and 1.2 million U in adults) should be given. Recurrence of ARF is most common within 2 years of the original attack but can occur at any time. The risk of recurrence decreases with age. Recurrence rates have been decreasing, from 20% in past years to 2% to 4% in more recent outbreaks. This decrease might be due to better surveillance and treatment.

PROPHYLAXIS

Antibiotic prophylaxis with penicillin should be started immediately after resolution of the acute episode. The optimal regimen consists of oral penicillin V potassium, 250,000 U twice a day, or parenteral penicillin G, 1.2 million U intramuscularly every 4 weeks. One study suggests, however, that injections every 3 weeks are more effective than every-4-week injections in preventing ARF recurrence.⁷³ If the patient is allergic to penicillin, erythromycin, 250 mg/day, can be substituted. If the patient is allergic to penicillin, a narrow-spectrum oral cephalosporin (e.g., cefadroxil, cephalexin) or an oral macrolide (e.g., erythromycin 250 mg per day) can be substituted. Because some penicillin-allergic persons (up to 10%) are also allergic to cephalosporins, these agents should not be used in patients with immediate (anaphylactic-type) hypersensitivity to penicillin.⁷⁴

The endpoint of prophylaxis is unclear; most authors believe it should continue at least until the patient is a young adult, which is usually 10 years from an acute attack with no recurrence. In our opinion, individuals with documented evidence of RHD should be on continuous prophylaxis indefinitely because our experience has been that ARF recurrences can occur even in the fifth or sixth decade. A potential problem for ARF recurrence involves young children in the household, who could transmit new group A streptococcal infection to RF-susceptible individuals. The alternative to long-term prophylaxis in an individual with ARF would be the introduction of streptococcal vaccines designed not only to prevent recurrent infection in

susceptible individuals with previous ARE, but also to prevent streptococcal disease in general.

STREPTOCOCCAL VACCINES

Difficulties associated with developing a streptococcal vaccine have been related mainly to the numerous reports that streptococcal antigens are known to cross-react with mammalian tissues.⁶⁵ Despite these caveats, more recent work indicates progress in this area. Perhaps the most advanced has been the work of Dale and colleagues,⁷⁵ in which investigators synthesized short peptides (20 to 30 amino acids) of many different M proteins, linked them together, and showed that they can develop type-specific antibodies that also are opsonic. Little toxicity or cross-reactivity to human tissues has been noted with the antigen or the antibodies.

A second approach revolves around the C-repeat region of the M protein moiety, which is common to all group A streptococci. Bessen and Fischetti⁷⁶ used a commensal organism commonly found in the oral mucosa of humans in which by genetic engineering they inserted the C-repeat of the M protein, which is preferentially displayed on the surface of the organism. This induces immunoglobulin (Ig) A antibodies, preventing oral colonization of mice by live group A streptococci. Bronze and colleagues⁷⁷ have confirmed these results using a different M-type organism. Golbus and Golbus⁷⁸ used similar methods, except that they inserted additional amino acids, making their antibodies opsonic.

Based on the observation by Ellis and colleagues³⁶ that human sera rarely, if ever, contain more than one type-specific M protein antibody, Salvadori and co-workers²⁷ examined other possible streptococcal antigens that might explain the broad-based immunity to streptococcal infection that occurs with increasing age. Their studies indicate that the streptococcal group A carbohydrate (GRA-CHO) might be a good immunogen for the following reasons. Antibodies to GRA-CHO are present in human sera, increase with age, and are opsonic for several distinct M⁺-type strains. Active and passive immunization with GRA-CHO in mice provided protection against a live lethal challenge in mice. No cross-reactive antibodies have been detected.

Two other candidates also are under consideration. Gerber and associates⁷⁴ described a surface antigen present on group A streptococci called *C5a peptidase*. This enzyme specifically cleaves the human serum chemotoxin C5a at the polymorphonuclear binding site. These observations led to experiments in which intranasal inoculation with C5a peptidase resulted in the appearance of antibodies that clearly reduced the potential of several different M⁺ strains to colonize mice.⁷⁴ Finally, Lukomski and colleagues⁷⁹ showed that the presence of SPEB markedly increases the virulence of a given group A streptococcal strain. Inactivation of the SPEB gene markedly decreases the lethality (IP challenge) of at least two strains—type 49 and S43 type 6. The mechanism whereby SPEB[−] strains decrease the lethality of the strain seems to be related to the fact that polymorphonuclear neutrophils were able to clear the mutant

strain from the circulation and tissues much more rapidly than the wild-type strain.⁷⁹

CONCLUSION

Despite its disappearance in many areas of the world, ARF continues to be a serious problem in the geographic areas inhabited by two-thirds of the population. In developed countries with full access to medical care, better nutrition, and housing, resurgence of the disease emphasizes the need for continued vigilance of physicians and other health officials in diagnosing and treating ARF. Whether this resurgence represents a change in the virulence of the organism or failure to recognize the importance and adequate treatment of an antecedent streptococcal infection remains an area of intense debate and requires careful and controlled epidemiologic surveillance.

The importance of early diagnosis and therapy cannot be overemphasized. Joint manifestations may be transient and self-limited; however, cardiac sequelae may be chronic and life threatening. Nevertheless, ARF remains one of the few autoimmune disorders known to occur as a result of infection with a specific organism. The confirmed observation of increased frequency of a B cell alloantigen in several populations of rheumatic patients suggests that it might be possible to identify at birth individuals who are susceptible to ARF. If so, from a public health standpoint, (1) these individuals would be prime candidates for immunization with any streptococcal vaccine that might be developed in the future; (2) careful monitoring of streptococcal disease in the susceptible population could lead to early and effective antibiotic strategies, resulting in disease prevention; and (3) in individuals previously infected, who later present with subtle or nonspecific manifestations of the disease, the presence or absence of the marker could be valuable in arriving at a diagnosis.

Continued study of ARF as a paradigm for microbial-host interactions has important implications for the study of autoimmune diseases in general, and rheumatic diseases in particular. Further insight into this intriguing host-parasite relationship may shed additional light on diseases in which infection is presumed but has not yet been identified.

Amyloidosis

DAVID C. SELDIN • MARTHA SKINNER

KEY POINTS

Amyloidosis is the term for systemic disease in which aggregated proteins form extracellular fibrils in tissues of the body, eventually leading to organ failure and death if not effectively treated.

Patients with amyloidosis can present with joint symptoms and soft tissue deposits that mimic rheumatologic disorders, and inadequately controlled rheumatologic disease or chronic infection can lead to secondary AA amyloidosis.

The diagnosis of amyloidosis requires a tissue biopsy that demonstrates green birefringence of deposits using polarization microscopy after staining with Congo red.

Appropriate treatment depends upon accurate biochemical or immunochemical identification of amyloid type, distinguishing hereditary from acquired forms of amyloidosis.

The term *amyloidosis* includes diseases that have in common the extracellular deposition of insoluble fibrillar proteins in tissues and organs. These diseases are a subset of a growing group of disorders recognized to be caused by misfolding of proteins; they include Alzheimer's and other neurodegenerative diseases, prion diseases, serpinopathies, some of the cystic fibroses, and others. A unifying feature of the amyloidoses is that the deposits share a common β -pleated sheet structural conformation that confers unique staining properties. The name "amyloid" is attributed to the pathologist Virchow, who in 1854 thought such deposits in autopsy livers were cellulose because of their peculiar staining reaction with iodine and sulfuric acid.¹ In the 20th century, amyloid was found to be a proteinaceous fibrillar deposit in tissues.² Biochemical characterization of fibril proteins from clinical cases proved the amyloidoses to be diverse diseases, many with a potentially fatal outcome owing to progressive deposition of amyloid fibrils in major organs. A growing number of treatments are available to target the source of the abnormal protein and, for some types, to inhibit the amyloidogenic protein misfolding process.

CLASSIFICATION AND EPIDEMIOLOGY

Amyloid diseases are defined by the biochemical nature of the protein in the deposited fibril. The proteins are diverse and are unrelated in primary amino acid sequence, resulting in classification of amyloid diseases according to whether they are systemic or localized, acquired or inherited; their recognized clinical patterns also determine how they are classified (Table 116-1).³ Each amyloid disease has a shorthand nomenclature, expressed as A for amyloidosis and an abbreviation for the biochemical nature of the fibrils; for example, AL is amyloid of immunoglobulin *light chain* origin. The discussion in this chapter is limited to the systemic amyloidoses because these are the diseases that can involve the joints and are potentially confused with autoimmune rheumatologic disorders.

The acquired systemic amyloidoses are AL (immunoglobulin light chain, or primary), AA (reactive, secondary), and A β_2 M (β_2 -microglobulin, dialysis-associated) types. The AL type is most common, although epidemiologic data are limited. One study based on National Center for Health Statistics data estimated the incidence as 4.5 per 100,000.⁴ AL amyloidosis usually manifests after age 40 years and is associated with rapid progression, multisystem involvement, and short survival. AA amyloidosis is rare, occurring in less than 1% of patients with chronic inflammatory diseases in the United States and Europe, but it is more common in Turkey and the Middle East, where it occurs in association with familial Mediterranean fever.⁵ As treatments for chronic inflammation and infection improve, the origin of AA amyloidosis appears to be shifting toward rare hereditary periodic fever syndromes or hematologic disorders associated with production of inflammatory cytokines such as Castleman's disease; workup should include genetic testing and imaging to screen for these conditions.⁶ The onset of AA amyloidosis is variable and can occur as soon as 1 year after the onset of an inflammatory disease or many years later, often corresponding to the degree of inflammation. It is the only type of amyloidosis that occurs in children, such as children with juvenile rheumatoid arthritis.⁷ A β_2 M amyloidosis is a chronic rheumatologic complication that occurs in a few patients on long-term dialysis and is related to a high concentration of β_2 -microglobulin.⁸

Table 116-1 Classification of Amyloidosis

Term	Fibril Composition	Systemic (S) or Localized (L)	Clinical Syndrome
AL	Immunoglobulin light chains (κ or λ)	S, L	Primary; myeloma-associated; systemic or localized in skin, lymph nodes, bladder, tracheobronchial tree
AA	Amyloid A protein	S	Secondary; reactive; familial Mediterranean fever
A β_2 M	β_2 -Microglobulin	S	Long-term hemodialysis or ambulatory peritoneal dialysis
ATTR	Transthyretin (106 familial variants); wild-type TTR in senile systemic amyloidosis	S	Familial amyloidotic polyneuropathy and cardiomyopathy; senile systemic amyloidosis
AApoA	Apolipoprotein A-I (16 familial variants) or apolipoprotein A-II (4 familial variants)	S	Familial polyneuropathy with nephropathy
AGel	Gelsolin (variant Asn 187, Tyr 187)	S	Familial polyneuropathy with lattice corneal dystrophy, cranial neuropathy, nephropathy
AFib	Fibrinogen A alpha (9 familial variants)	S	Familial amyloidosis with nephropathy
ALys	Lysozyme (5 familial variants)	S	Familial amyloidosis with nephropathy
A β	Amyloid β protein	L	Alzheimer's disease; Down syndrome; cerebral amyloid angiopathy (Dutch)
ACys	Cystatin C (variant with N-terminal deletion and Glu 68)	S	Cerebral amyloid angiopathy (Icelandic)
AIAPP	Islet amyloid polypeptide	L	Type 2 diabetes mellitus; insulinoma
ACal	Calcitonin	L	Medullary carcinoma of the thyroid
AANF	Atrial natriuretic factor	L	Atrial amyloid, localized

The inherited amyloidoses are rare autosomal dominant diseases in which a variant plasma protein forms amyloid deposits beginning in midlife.⁹ The most common form is caused by variant transthyretins (TTRs), of which more than 100 types are known to be associated with amyloidosis.¹⁰ One variant, with a substitution of isoleucine for valine at position 122 (V122I), has a carrier frequency that may be 4% in the black population and is associated with late-onset cardiac amyloidosis. Among a large cohort of African-Americans over age 65, the frequency of congestive heart failure and mortality was higher among those carrying the V122I gene than in age, gender, and ethnically matched controls.¹¹ In an amyloidosis referral population, African-Americans over age 60 who presented with amyloid cardiomyopathy were twice as likely to have TTR amyloidosis (ATTR) due to V122I as to have the more common AL type of amyloidosis.¹² Even wild-type TTRs can form fibrils, leading to senile systemic amyloidosis, which predominantly affects the heart, in older patients.¹³

PATHOLOGY AND PATHOGENESIS OF AMYLOID FIBRIL FORMATION

Pathologic Features

Amyloid deposits are widespread in AL amyloidosis and can be present in the extracellular spaces and blood vessels of all organs. Deposits in AA amyloidosis usually develop in the kidneys, liver, and spleen, although widespread deposits can be found late in the course of the disease. In A β_2 M amyloidosis, deposits tend to occur in synovial membrane, cartilage, and bone, but visceral organs are sometimes affected. In ATTR amyloidosis, the nervous system, heart, and thyroid are frequently affected organs, and only small deposits are found elsewhere.

All amyloid deposits stain with Congo red dye and exhibit a unique green birefringence by polarized light microscopy,¹⁴ although the deposits also can be recognized on routine hematoxylin and eosin-stained sections. By

electron microscopy, amyloid fibrils are 8 to 10 nm wide and of varying lengths, with a 2.5- to 3.5-nm filamentous subunit arranged along the long axis of the fibril in a slow twist.¹⁵ Typing of amyloid deposits can be done with conventional immunohistochemical staining. False-positive results can occur, however, owing to the presence of nonamyloid serum proteins, and immunoelectron microscopy can provide more definitive immunologic identification of the protein in the fibril, or the composition of extracted fibrils can be identified by mass spectrometric proteomic analysis.^{16,17}

Pathogenesis of Amyloid Fibril Formation

The exact mechanism of fibril formation is unknown and may differ among the various types of amyloid.¹⁸ Studies suggest a common underlying mechanism, however, in which a partially unfolded protein intermediate forms multimers and then higher-order polymers. Factors that contribute to fibrillogenesis include variant or unstable protein structure, extensive β -conformation of the precursor protein, proteolytic processing of the precursor protein, association with components of the serum or extracellular matrix (e.g., serum amyloid P [SAP] component, amyloid enhancing factor, apolipoprotein E, glycosaminoglycans), and physical properties such as pH of the tissue site.

AL amyloidosis is a plasma cell dyscrasia with an excess of clonal plasma cells in the bone marrow; it can occur in isolation or in combination with multiple myeloma. Similar cytogenetic changes have been identified in these plasma cell diseases, suggesting that they may have a common molecular pathogenesis.^{19,20} By two-dimensional gel electrophoresis and mass spectrometry, it can be seen that the amyloid fibril deposits are composed of intact 23-kD monoclonal immunoglobulin light chains and C-terminal truncated fragments.¹⁶ Although all κ and λ light chain subtypes have been identified in amyloid fibrils, λ subtypes predominate, and the λ 6 subtype seems to have unique structural properties that predispose it to fibril formation,²¹ often in the kidney.²² AL amyloidosis is usually a rapidly progressive disease with amyloid deposits in multiple tissue sites.

The AA type of amyloidosis is a complication of severe, long-standing inflammation, as occurs in chronic inflammatory disorders or infections. AA amyloid fibrils usually are composed of an 8-kD, 76 amino acid amino-terminal portion of the 12-kD precursor, serum amyloid A (SAA).²³ SAA is a polymorphic protein encoded by a family of SAA genes, which are acute phase apoproteins synthesized in the liver and transported by a high-density lipoprotein, HDL3, in the plasma.²⁴ An underlying inflammatory disease of several years' duration causing an elevated SAA usually precedes fibril formation, although infection can produce AA deposition more quickly. AA fibril formation can be accelerated by an amyloid enhancing factor present in high concentration in the spleen (which may be early SAA aggregates or deposits), by basement membrane heparan sulfate proteoglycan, or by seeding with AA or heterologous fibrils.^{25,26}

Factors related to β_2 -microglobulin fibril formation are under investigation. The high prevalence of $A\beta_2M$ disease in patients undergoing long-term dialysis argues against an amyloidogenic variant β_2 -microglobulin molecule. The permeability of dialysis membranes may be a factor because the molecular weight of β_2 -microglobulin is 11.8 kD—above the porosity of standard membranes. It has been hypothesized that dialysis membranes may be bioincompatible and may induce proinflammatory mediators that stimulate β_2 -microglobulin and contribute to fibril formation.²⁷

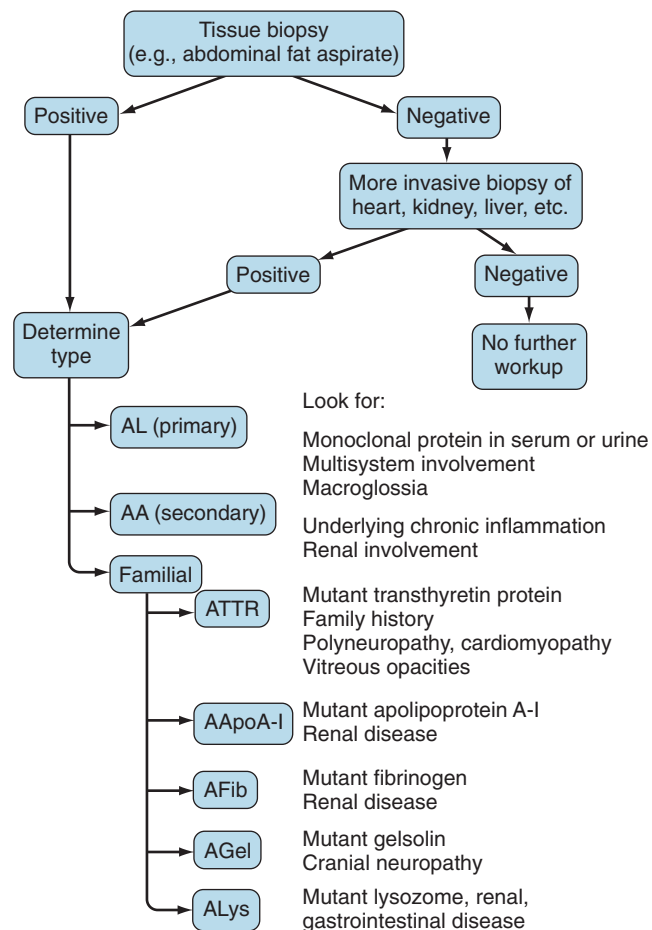

Figure 116-2 Subcutaneous fat aspirate stained with Congo red viewed by light microscopy (A) and polarized light (B) ($\times 200$). Staining and birefringence are evident in the walls and connective tissues surrounding the adipose cells.

In ATTR (also called *familial amyloidotic polyneuropathy*) and all other forms of familial amyloidosis, inherited mutations or polymorphisms in the genes encoding large serum proteins produce amyloid-prone variants. The process of fibrillogenesis has been best studied for TTR, in which variant TTR molecules seem to be prone to dissociation from stable tetramers and to unfolding, leading to misfolding, polymerization, and fibril formation.²⁸ The role of aging is intriguing because patients with variant proteins do not have clinically apparent disease until midlife or later, despite the lifelong presence of the abnormal protein.²⁹ Further evidence of an age-related trigger is that senile cardiac amyloidosis, caused by the deposition of fibrils derived from normal TTR, is exclusively a disease of elderly individuals.¹³

DIAGNOSIS

A tissue biopsy specimen showing amyloid fibrils is necessary for the diagnosis of amyloidosis (Figure 116-1). The least invasive biopsy is the abdominal fat aspirate, which is positive in 80% to 90% of patients with AL or ATTR amyloidosis and in 60% to 70% of patients with AA amyloidosis.^{30,31} It is easy to perform after local injection of anesthetic and has a low rate of infectious or hemorrhagic complications (Figure 116-2). If the aspirate is negative, but clinical suspicion for disease persists, a more invasive tissue biopsy should be done. Although a biopsy specimen of a clinically involved organ is recommended, almost any tissue biopsy specimen is likely to be positive if the patient has systemic amyloidosis: In a series of 100 patients with AL amyloidosis, 85% of 249 tissue biopsy specimens were positive, including

Figure 116-3 **A**, Pretreatment serum immunofixation electrophoresis (ELP) shows an IgG (G) κ monoclonal protein. **B**, Post-treatment serum immunofixation electrophoresis shows absence of the monoclonal protein. A, IgA; K, kappa chain; L, lambda chain; M, IgM.

all samples from the kidney, heart, and liver.³² When the diagnosis of amyloidosis is made, careful evaluation of the entire clinical picture, including manner of presentation, organ system involvement, underlying disease, and family history, should provide a clue to the type of amyloid.

Identification of a plasma cell dyscrasia distinguishes AL from other types of amyloidosis (Figure 116-3). More than 90% of patients have a serum or urine monoclonal immunoglobulin protein or a free light chain on testing by immunofixation electrophoresis or by a recently available nephelometric assay for free light chains.^{33,34} In addition, the percentage of plasma cells in the bone marrow is often increased; these are monoclonal on immunohistochemical staining (Figure 116-4).³⁵ A monoclonal serum protein by itself is not diagnostic of amyloidosis because monoclonal gammopathy of uncertain significance is common in older patients. When monoclonal gammopathy of uncertain significance is present in a patient with biopsy-proven amyloidosis, however, the AL type is strongly suspected. Immunohistochemical staining by light or electron

microscopy should be done by a laboratory familiar with the techniques and able to perform appropriate controls. Mass spectrometry–based microsequencing of small amounts of protein extracted from fibril deposits ultimately may be the most reliable way to identify the components of the fibrils.^{16,17} AA amyloidosis is suspected in patients with renal amyloidosis and a chronic inflammatory condition or infection. AL and ATTR amyloidosis must be ruled out. AA amyloidosis must be confirmed by immunohistochemical staining for AA protein.

Familial amyloidosis must be excluded in every patient who does not have a plasma cell dyscrasia or the AA type of amyloidosis. Although the disease has a dominant inheritance, family history may not be apparent when the disease occurs later in life; also, some cases occur through new mutations. Variant TTR proteins usually can be detected by isoelectric focusing (Figure 116-5).³⁶ Abnormal isoelectric focusing should prompt genetic testing to determine the precise TTR mutation. Genetic testing should be employed when screening tests fail to identify the fibril protein. With the use of polymerase chain reaction–based sequencing, abnormal fibrinogens and apolipoproteins and variant TTRs can be detected.³⁷

A novel renal amyloid protein, leukocyte chemotactic factor 2 (LECT2), has been found in glomeruli, renal vessels, and interstitium in patients with isolated renal amyloidosis and should be considered in patients who are negative for the more common types of amyloidosis.³⁸

CLINICAL FEATURES AND TREATMENT OF THE SYSTEMIC AMYLOIDOSES

AL Amyloidosis

AL amyloidosis usually occurs in middle-aged or older individuals but also can occur in the third or fourth decade of life. It has a wide spectrum of organ system involvement, and presenting features reflect the organs most prominently affected.^{39,40} Initial symptoms of fatigue and weight loss are frequent, but the diagnosis is rarely made until symptoms referable to a specific organ appear.

The kidneys are commonly affected; renal amyloidosis is manifested by proteinuria, sometimes massive, with edema and hypoalbuminemia. Mild renal dysfunction is frequent, but rapidly progressing renal failure is rare. Cardiac

Figure 116-4 Bone marrow biopsy specimen stained with antibody to λ light chain shows predominance of λ plasma cells and staining of amyloid deposit around a blood vessel ($\times 400$).

Figure 116-5 Isoelectric focusing of serum samples shows two bands of variant and wild-type transthyretin (TTR) protein from a patient with TTR amyloidosis (lane 2) and a single band of wild-type TTR in normal subjects (lanes 1 and 3, indicated with an arrow).

involvement, often with congestive heart failure, is a common presentation.⁴¹ The electrocardiogram may show low voltage with a pattern of myocardial infarction. The echocardiogram frequently shows concentrically thickened ventricles and a normal or mildly reduced ejection fraction. Nervous system features include peripheral sensory neuropathy, carpal tunnel syndrome, and autonomic dysfunction with gastrointestinal motility disturbances (early satiety, diarrhea, constipation) and orthostatic hypotension. Macroglossia, a classic feature pathognomonic of AL amyloidosis, is found in 10% of patients (Figure 116-6). Hepatomegaly may be massive with mild cholestatic abnormalities of liver function, although liver failure is uncommon, even when hepatomegaly is massive. The spleen is frequently involved, and functional hyposplenism may occur, even in the absence of significant splenomegaly. Cutaneous ecchymoses are common, particularly around the eyes, giving the “raccoon-eyes” sign, and appear spontaneously or when provoked by minor trauma (Figure 116-7). Other findings include nail dystrophy (Figure 116-8), alopecia, and amyloid arthropathy with thickening of synovial membranes. We

Figure 116-6 Enlarged tongue of a patient with AL amyloidosis.

Figure 116-7 Periorbital ecchymoses in a patient with AL amyloidosis.

have reviewed the soft tissue and joint manifestations of AL amyloidosis in a series of almost 200 patients.⁴² Symptoms and signs mimicking rheumatologic diseases, with arthropathy, subcutaneous tissue deposits, muscle pseudohypertrophy, adenopathy, carpal tunnel syndrome, submandibular gland enlargement, and macroglossia, occur in more than 40% of patients with AL amyloidosis.

Timely diagnosis of AL amyloidosis is crucial. Patients with any of these clinical syndromes should be screened for amyloid deposition and for a plasma cell disorder as previously described. Note that the sensitivity of serum or urine protein electrophoresis (SPEP and UPEP) without immunofixation is poor; these tests alone are not useful for excluding or diagnosing AL amyloidosis.

Extensive multisystem involvement typifies AL amyloidosis, and median survival with no treatment is usually only about 1 year from diagnosis. Current therapies target clonal bone marrow plasma cells using chemotherapy approaches employed for multiple myeloma (Table 116-2). Oral melphalan and prednisone constituted the first regimen tried for AL amyloidosis; it was minimally effective^{32,43} and is rarely used today because recent studies show that substitution of high-dose dexamethasone for prednisone seems to increase response rates significantly.⁴⁴

High-dose intravenous melphalan followed by autologous stem cell transplantation is highly effective. Of more than 500 patients treated on such protocols at Boston Medical Center, approximately 40% of evaluable patients had achieved a hematologic complete response when assessed at 1 year post treatment; most experienced significant improvement or stabilization of organ function.⁴⁵ Median survival in treated patients exceeds 4.5 years and

Figure 116-8 Fingernail dystrophy in a patient with AL amyloidosis.

Table 116-2 Major Treatment Options for Amyloidosis

AL Amyloidosis
Intravenous melphalan with autologous stem cell rescue Granulocyte colony-stimulating factor–mobilized peripheral blood stem cell collection Intravenous melphalan 140–200 mg/m ² Autologous stem cell reinfusion
Cyclic oral melphalan and dexamethasone Melphalan 0.22 mg/kg/day × 4 days Dexamethasone 20–40 mg/day × 4 days, or weekly Repeat administration every 4 weeks
Immunomodulators Lenalidomide 5–15 mg/day × 21 days Dexamethasone 20–40 mg/day weekly Repeat administration every 4 weeks
Proteasome inhibitors Intravenous bortezomib, 0.7–1.6 mg/m ² 1–2 times per week Repeat every 3–5 weeks
AA Amyloidosis
Aggressive treatment of underlying inflammatory disease Medical or surgical treatment of underlying infection Colchicine 1.2–1.8 mg/day for AA amyloidosis secondary to familial Mediterranean fever Antifibril drug, eprodisate (investigational)
ATTR Amyloidosis
Orthotopic liver transplantation Transthyretin stabilizers: tafamadis, diflunisal (investigational)

is durable.⁴⁶ Other referral centers have found similar results.^{47–49} However, patients with amyloidosis and organ impairment have high rates of treatment-related morbidity and mortality with aggressive treatment. Factors that contribute to mortality include amyloid cardiomyopathy, poor performance or nutritional status, reduced pulmonary function, and amyloid-associated bleeding disorders. The only randomized multicenter study comparing oral melphalan chemotherapy with intravenous (IV) melphalan chemotherapy with stem cell support was plagued by high treatment-related mortality and failed to show benefit for the high-dose regimen.⁵⁰ At experienced centers, this treatment is still considered first-line in low-risk patients. Age alone⁵¹ or renal failure⁵² does not exclude patients from such treatment. Cardiac biomarkers have been used to stratify risk for high-dose therapy.⁵³

For patients with significantly impaired cardiac function or arrhythmias resulting from amyloid involvement of the myocardium, median survival is only about 6 months without treatment, and stem cell mobilization and high-dose chemotherapy are associated with great morbidity. In such patients, orthotopic cardiac transplantation followed by intravenous melphalan and stem cell rescue to prevent fibrillogenesis in the transplanted heart or other organs can be effective.⁵⁴

New agents that are efficacious in reducing the plasma cell burden in multiple myeloma are being tested for AL amyloidosis. These include immunomodulators such as lenalidomide^{55–57} that affect the bone marrow microenvironment, as well as proteasome inhibitors to which plasma cells are particularly sensitive, such as bortezomib.^{58–60} These agents generally have been tested for use in patients for whom alkylator chemotherapy has failed; current clinical

trials are examining these novel agents in combination with alkylators, as induction before transplant, and for maintenance. Weekly rather than bi-weekly dosing of bortezomib appears to reduce the incidence of peripheral neuropathy and may be safer in AL amyloidosis patients. Innovative approaches target the amyloid fibrils themselves or accessory binding proteins. The anthracycline derivative 4'-iodo-4'-deoxydoxorubicin (IDOX) was noted to cause resorption of amyloid deposits in model systems, but clinical trials have failed to show any clinical benefit.⁶¹ The agent R-1-[6-[R-2-carboxy-pyrrolidin-1-yl]-6-oxo-hexanoyl]pyrrolidine-2-carboxylic acid (CPHPC) binds serum amyloid P protein and accelerates clearance from the circulation and from amyloid fibrils in animal models,⁶² but it has not been proven to provide any clinical benefit on its own. In animal models, the addition of component antibody against SAP appears to further accelerate clearance, and clinical trials with this combination are being planned.⁶³ Supportive treatment is recommended for patients with all types of amyloidosis (Table 116-3). At times, supportive treatment may be lifesaving (e.g., heart or kidney transplantation, renal dialysis, cardiac pacemaker, nutritional support). Digitalis, calcium channel blockers, and β -blockers are relatively contraindicated because toxicity has been observed at therapeutic levels.

AA Amyloidosis

AA amyloidosis can occur at any age. The primary clinical manifestation is proteinuria or renal insufficiency or both.⁵ A study from Finland found AA amyloidosis to be the most common cause of nephrotic syndrome in patients with rheumatoid arthritis.⁶⁴ Hepatomegaly, splenomegaly, and autonomic neuropathy frequently occur as the disease progresses; cardiomyopathy occurs rarely. With chronic inflammatory diseases, amyloid progression is slow, and survival is often longer than 10 years, particularly with treatment for end-stage renal disease. In contrast, untreated infections, such as osteomyelitis, tuberculosis, or leprosy, can produce a more rapidly progressive amyloid syndrome, which remits with effective medical or surgical treatment of the infection.

The major therapy in AA amyloidosis is treatment of the underlying inflammatory or infectious disease. Treatment that suppresses or eliminates the inflammation or infection also decreases the SAA protein. For familial Mediterranean fever, colchicine, 1.2 to 1.8 mg/day, is the appropriate treatment. Colchicine has not been helpful for AA amyloidosis of other causes or for other amyloidoses. A multicenter randomized trial using a new anti-amyloid drug, eprodisate, has been completed; the drug was found to significantly delay worsening of renal function in patients with AA amyloidosis.⁶⁵ A second multicenter trial requested by the Food and Drug Administration (FDA) is now underway. Eprodisate interferes with the interaction of AA amyloid protein and glycosaminoglycans in tissues and prevents fibril formation and deposition.

A β ₂M Amyloidosis

Several distinct rheumatologic conditions are observed in A β ₂M amyloidosis, including carpal tunnel syndrome, persistent joint effusions, spondyloarthropathy, and cystic bone

Table 116-3 Supportive Treatment for All Types of Amyloidosis

Organ System	Symptom	Treatment Options
Cardiac	Congestive failure	Salt restriction of 1-2 g/day Diuretics: furosemide, spironolactone, metolazone
	Arrhythmia	Pacemaker Automatic implantable cardiac defibrillator Antiarrhythmics
Renal	Nephrotic syndrome	Salt restriction of 1-2 g/day Elastic stockings, leg elevation Maintaining dietary protein Angiotensin-converting enzyme inhibitor, if blood pressure tolerates Dialysis (long-term ambulatory peritoneal dialysis or hemodialysis)
Autonomic nervous	Renal failure	Midodrine
	Orthostatic hypotension	Increased dietary salt or added fludrocortisone, depending on edema Elastic stockings
Gastrointestinal	Gastric atony or ileus	Small frequent feedings (6/day) low in fat Oral nutritional supplements Jejunostomy tube feeding Parenteral nutrition
		Low-fat diet (≤ 40 g)
		Psyllium hydrophilic mucilloid (Metamucil)
		Loperamide hydrochloride (Imodium)
	Diarrhea	Tincture of opium Parenteral nutrition
Peripheral nervous	Macroglossia	Soft solid diet Partial glossectomy (rarely effective)
		Avoiding trauma
	Sensory neuropathy	Gabapentin (Neurontin) 100-300 mg 3 times daily Amitriptyline 25-50 mg at bedtime Pregabalin (Lyrica) 50-100 mg 3 times daily
		Ankle-foot orthotics for footdrop
		Physical therapy
Hematologic	Intracutaneous bleeding	Avoiding trauma, antiplatelet agents
	Factor X deficiency	Factor replacement (recombinant factor VIIa, prothrombin complex concentrates) Splenectomy for splenomegaly

lesions. Carpal tunnel syndrome is usually the first symptom of disease. Persistent joint effusions accompanied by mild discomfort occur in 50% of patients on dialysis for longer than 12 years. Involvement is bilateral, and large joints (shoulders, knees, wrists, and hips) are more frequently affected. The synovial fluid is noninflammatory, and β_2 -microglobulin amyloid deposits can be found if the sediment is examined with Congo red staining. Spondyloarthropathy with destructive changes in the intervertebral disks and paravertebral erosions have occurred in association with β_2 -microglobulin amyloid deposits. Cystic bone lesions sometimes leading to pathologic fractures have been described in the femoral head, acetabulum, humerus, tibial plateau, vertebral bodies, and carpal bones. Although less common, visceral β_2 -microglobulin amyloid deposits occasionally occur in the gastrointestinal tract, heart, tendons, and subcutaneous tissues of the buttocks.

Treatment for $A\beta_2M$ amyloidosis is difficult to provide because the 11-kD β_2 -microglobulin molecule is too large to pass through a dialysis membrane. Consistent with a postulated role of copper in initiating $A\beta_2M$ fibrillogenesis,⁶⁶ copper-free dialysis membranes seem to reduce the incidence of disease. Patients on continuous ambulatory peritoneal dialysis usually have lower plasma levels of β_2 -microglobulin than patients on hemodialysis and may not develop amyloid deposits as quickly. Symptoms of arthropathy are common, and prevalence may approach 100% of individuals on dialysis for longer than 15 years. Patients who have received kidney transplants after developing $A\beta_2M$ report improvement in symptoms.

ATTR Amyloidosis

The clinical features of ATTR amyloidosis overlap AL amyloidosis such that the diseases cannot be reliably distinguished on clinical grounds alone. A family history makes ATTR more likely, but many patients seem to present sporadically with new mutations. Within each family, disease begins at nearly the same age, and symptoms usually include neuropathy or cardiomyopathy or both. Peripheral neuropathy begins as a lower extremity sensory and motor neuropathy and progresses to the upper extremities. Autonomic neuropathy is manifested by gastrointestinal symptoms of diarrhea with weight loss and orthostatic hypotension. Cardiomyopathy and conduction system defects are similar to those caused by AL amyloidosis, although in ATTR, heart failure is less common, and the prognosis is better.⁶⁷ Vitreous opacities caused by amyloid deposits are pathognomonic of ATTR amyloidosis.

The TTR variant, V122I, is a common allele in African-Americans and is associated with cardiomyopathy. In a large referral population, 25% of African-American patients with amyloidosis had this TTR variant.^{11,12} ATTR due to V122I is likely underdiagnosed because of lack of physician awareness and the difficulty of distinguishing amyloid and hypertensive cardiomyopathy without an endomyocardial biopsy.

Without intervention, survival after ATTR disease onset is 5 to 15 years. Orthotopic liver transplantation, which removes the major source of variant TTR production and replaces it with normal TTR, is the major treatment for ATTR amyloidosis.^{68,69} Liver transplantation arrests disease

progression, and some improvement in autonomic and peripheral neuropathy may occur.⁷⁰ Cardiomyopathy does not improve and in some patients seems to worsen after liver transplantation.⁷¹ A beneficial long-term outcome depends on transplantation early in the disease course.⁷² Two international multicenter randomized placebo-controlled clinical trials have been conducted to test the efficacy of the nonsteroidal anti-inflammatory drug, diflunisal, and its analog tafamidis, for the treatment of ATTR amyloidosis (www.bu.edu/amyloid/doctors/trials/html) based on laboratory studies showing that these agents stabilize TTR and prevent unfolding and aggregation.⁷³ Antisense and small interfering RNA approaches are also being developed.

SUMMARY

Timely and accurate diagnosis of amyloidosis is essential because effective treatments for some forms of amyloidosis are available or are undergoing clinical trials. The first step is recognition of a clinical syndrome consistent with amyloidosis; this is followed by an appropriate biopsy or fat aspirate to identify tissue fibrils. The next priority should be to determine whether an associated plasma cell disorder can be identified, because AL is the most rapidly progressive type of systemic amyloidosis, and therapy should be initiated before heart, kidney, or liver failure occurs. Definitive identification of the amyloid precursor protein is essential for appropriate therapy, and amyloid referral centers can provide specialized diagnostic techniques and access to clinical trials. An understanding of the biophysical properties of amyloid proteins and of the mechanisms of protein misfolding and tissue damage will enable the further development of more specific and less toxic anti-amyloid therapeutics.

KEY POINTS

Sarcoidosis is a heterogeneous multisystem inflammatory disease of unknown cause characterized by the development and accumulation of noncaseating granulomata in any organ system.

Sarcoidosis occurs worldwide and affects people of all racial and ethnic backgrounds.

The pathogenesis of sarcoidosis likely involves the interplay of different cells, cytokines, and other inflammatory mediators.

Rheumatologic manifestations are common in sarcoidosis and are often overlooked or misdiagnosed.

No treatments have been FDA-approved for sarcoidosis or for any of its manifestations, including sarcoid arthritis.

New treatment modalities, including tumor necrosis factor (TNF) inhibitors, appear to be promising for the treatment of extrathoracic sarcoidosis based on case series, although randomized controlled trials have shown limited benefit in cases of pulmonary involvement.

Sarcoidosis is an orphan, systemic, clinically heterogeneous disorder. Its cause has yet to be identified, but environmental, genetic, and infectious causes have been suggested. The hallmark of sarcoidosis is the development and accumulation of noncaseating granulomas in any organ system. Organ system involvement, which is unpredictable and varies between patients, is the major determinant of morbidity and mortality in sarcoidosis. Although any organ system can be involved, the lungs are affected in most cases. Lymphatic, skin, and ocular findings are also common. Given the variability of sarcoidosis manifestations, diagnosing this disorder is often difficult. Patients may be asymptomatic or may present with a range of nonspecific symptoms, but specific symptoms such as cough, dyspnea, burning of eyes, or rash may suggest the diagnosis.¹ When extrapulmonary symptoms develop, they sometimes result in rheumatologic manifestations including but not limited to arthritis, skin lesions, arthralgias, and neuropathy.²

EPIDEMIOLOGY

Sarcoidosis is a global disease. Because of its clinical heterogeneity and its variable diagnostic criteria in different countries, the worldwide prevalence and incidence of sarcoidosis have been difficult to calculate. In Northern Europe, up to 40 cases per 100,000 people have been reported.^{3,4} A study from Eastern Europe found only 3.68 cases of sarcoidosis per

100,000 people.⁵ The incidence of sarcoidosis in Japan is also low, with one study estimating it at 3.7 cases per 100,000 individuals.⁶ Within countries, incidence rates may vary between races. In the United States, the annual incidence of sarcoidosis is more than three times higher in black individuals (35.5 per 100,000) than in white people (10.9 per 100,000).⁷ Furthermore, the disease course of sarcoidosis is more progressive and may be more fatal in black Americans.^{8,9} Despite numerous epidemiologic studies of sarcoidosis, many clinicians and researchers believe that estimates of prevalence and incidence are lower than actual rates of the disease owing to inaccurate diagnoses or asymptomatic cases that are never diagnosed.

Although sarcoidosis affects men and women of all ages and from diverse ethnic backgrounds,^{4,10} some disparities in how it affects these groups have been noted. The fact that it affects slightly more women than men has been confirmed in studies from around the world; estimates indicate that 57% of patients with sarcoidosis are women.⁴ Relative to men, women with sarcoidosis have a greater number of ocular and neurologic manifestations. People of any age may acquire the disease, but the median age of onset is around 40.⁴ A second peak of incidence has been reported around age 65, especially in women.^{8,11}

IMMUNOPATHOGENESIS

The pathogenesis of sarcoidosis likely involves the interplay of many different cells, cytokines, and other inflammatory mediators. Granuloma development is the characteristic pathologic feature of tissue involvement in sarcoidosis. Physiologically, granulomas act as shields, protecting tissues from pathogens, thereby pre-empting inflammatory reactions. Their formation is the end product of a coordinated effort involving T cell activation, antigen-presenting cell (APC) activation, and cell signaling. Granulomas consist of a core of mononuclear phagocytes, such as epithelioid cells, multinucleated giant cells, and macrophages, which are encased by lymphocytes, including B cells, CD4⁺ T cells, and CD8⁺ T cells.¹²

Innate Immunity

T cell activation is required for granulomas to form. Early in the course of sarcoidosis, an unknown antigen or multiple antigens activate T cells and macrophages, thereby triggering downstream signaling from both cell types. Locally activated CD4⁺ T helper cells differentiate into T helper type 1 (Th1)-like cells, causing subsequent elevations in Th1-associated inflammatory mediators, such as interleukin (IL)-2, interferon (IFN)- α , IFN- γ , monocyte chemotactic

protein-1 (MCP-1), macrophage inflammatory protein-1 (MIP-1), and granulocyte-macrophage colony-stimulating factor (GM-CSF). CD4⁺ T helper cells also interact with APCs to initiate the development of and preserve granulomas.³ Thus, T cells undergo oligoclonal proliferation in areas of immune system activity. At this point in the disease process, lymphocyte levels are typically increased, and the ratio of CD4/CD8 cells becomes elevated in the lungs and other affected organs.

Acquired Immunity

In sarcoidosis, uptake of antigens is the most likely trigger for activation of macrophages, which are then able to produce IL-12, IL-15, IL-18, and tumor necrosis factor (TNF). Macrophage-derived cytokines contribute to the external signaling milieu that selectively pressures toward Th1 differentiation of CD4⁺ cells.^{12,13} Ultimately, a feedback loop from downstream-produced cytokine cascade induces macrophages to differentiate into epithelioid cells, which gain secretory capability, lose phagocytic capacity, and fuse to form multinucleated giant cells.³ These epithelioid cells form the cellular basis of granulomas. Also contributing to granuloma formation are Th2 cells. These cells synthesize fibronectin and CC motif ligand 18 (CCL18). Release of these mediators results in a positive feedback loop of CCL18-activated and macrophage-mediated collagen formation. Although granulomas spontaneously resolve without causing damage in most cases, this cycle leads to fibrosis in up to 25% of patients with sarcoidosis.³ As patients' fibrosis becomes more extensive, their prognosis worsens. Although the mechanisms responsible for granuloma fibrosis have not been fully characterized, patterns of cytokines change, and Th2 cells may pressure toward an increased ratio of CD8 to CD4 cells. Less than 5% of patients die from sarcoidosis, but fibrosis leading to respiratory failure is a contributing factor in many sarcoidosis deaths.

In summary, the essential immunologic events in granuloma formation can be summarized as follows^{13,14}: (1) antigen exposure, (2) antigen processing and presentation by macrophages, resulting in T cell immunity against the antigen, (3) T-effector cell production, (4) macrophage activation, and (5) granuloma formation.

ETIOLOGY

Sarcoidosis has yet to be attributed to a single factor. The heterogeneity of the disease suggests that multiple causative agents may be responsible for the variable disease manifestations of sarcoidosis. Given the immunopathogenic mechanisms that underlie sarcoidosis, such a disease trigger might be a T cell antigen that stimulates the cascade of events leading to granuloma formation. Because the lungs are affected in more than 90% of cases of sarcoidosis, it is likely that an environmental agent (including an infectious agent, potentially exposed via the pulmonary route) might contribute to onset of sarcoidosis.

Both inorganic and organic environmental factors with antigenic capabilities have been implicated in the pathogenesis of sarcoidosis. Early studies on the causes of sarcoidosis suggested a link between sarcoidosis and agents

associated with a rural lifestyle, such as the lumber industry and burning wood.^{15,16} These data have been extended in the ACCESS study, which found that agricultural debris and wood burning are associated particularly with pulmonary sarcoidosis but not with systemic sarcoidosis.¹⁷ In a different analysis of the ACCESS trial, radiation, insecticides, mildew, and mold were environmental factors associated with systemic sarcoidosis phenotype.¹⁸ These findings may indicate that each of these unique sarcoidosis subtypes has its own causes.

Numerous methods have been used to look for an infectious agent as a cause of sarcoidosis. When in situ hybridization was used, *Mycobacterium tuberculosis* catalase-peroxidase protein (mKatG) was found in nearly 40% of tissue samples from patients with sarcoidosis. Recombinant mKatG protein was then used to measure mKatG antibodies in patients with sarcoidosis, which were present in 50% of patients studied.¹⁹ Others have found evidence of an immunologic reaction to additional mycobacterial antigens.^{20,21} *Propionibacterium acnes* has been found more frequently in granulomas from sarcoidosis patients but can also be found in individuals without sarcoidosis, so its primary role in pathogenesis remains unclear.²²⁻²⁴ These studies suggest that sarcoidosis may represent overexposure of the patient to a commonly encountered microorganism associated with dysregulated resultant immune responses. Because several types of bacteria have been associated with sarcoidosis, some clinicians have attempted to use antibiotics to manage the disease. Although skin sarcoidosis has, on occasion, responded to antibiotics,²⁵ their usefulness in other forms of sarcoidosis appears minimal.²²

GENETICS

Compelling studies of familial clustering and incidence of sarcoidosis among different racial groups indicate that sarcoidosis susceptibility is influenced by the interplay of genetic factors. In the ACCESS study, first-degree relatives were reported to have a fivefold increase in risk of developing the disease.²⁶ Associations have been found between risk of sarcoidosis and class I and II human leukocyte antigen (HLA) gene products, which have essential roles in antigen presentation. It is considered likely that a susceptibility locus for sarcoidosis exists within the HLA gene region, as is the case with other autoimmune diseases and cancers such as Hodgkin's lymphoma. An intriguing analysis of data from the ACCESS study identified associations between genetic factors (HLA alleles), environmental factors, and sarcoidosis phenotypes. In considering together several of the factors postulated to cause sarcoidosis, a compelling argument can be made for a genetic factor that predisposes individuals to the disease and a subsequent environmental exposure that triggers onset of sarcoidosis. Specifically, Rossman and colleagues found that HLA-DRB1*1101 and insecticide exposure at work are significantly associated with cardiac sarcoidosis and hypercalcemia.²⁷ A similar relationship between HLA-DRB1*1101, mold and musty odors, and pulmonary sarcoidosis was described.²⁷

HLA polymorphisms have also been linked to Löfgren's syndrome, an acute form of sarcoidosis characterized by bilateral hilar lymphadenopathy (BHL), erythema nodosum (EN), fever, and periarticular ankle inflammation or

arthritis of the ankle. In patients with Löfgren's syndrome, HLA-DRB1*03 is four times more common than in healthy individuals²⁸ and has been associated with EN and ankle arthritis, which are favorable prognostic factors. A more recent study found that DRB1*03-positive and DRB1*03-negative patients have different disease courses. For example, most DRB1*03-positive patients experienced resolution of Löfgren's syndrome within 2 years after diagnosis. By contrast, nearly half of patients without this allele had resolving disease.²⁹ The mechanism underlying this difference in disease course remains unknown. A relationship between HLA-DRB1*03 and interferon- γ -3,3 homozygosity has been suggested in sarcoidosis. Wysoczanska and colleagues reported that when combined, these two genetic factors increase the risk of Löfgren's syndrome, and this may be indicative of a complex gene-gene interaction underlying this sarcoidosis phenotype.³⁰

Genetic studies of non-HLA genes have been inconclusive. Loci coding for TNF, co-stimulatory molecules on antigen-presenting cells such as CD80 and CD86, chemokine receptors CCR2 and CCR5, and many others have been suggested as possible susceptibility factors, but their roles have not been fully characterized.^{22,31} Of these, chemokine receptor genes have been associated with particular sarcoidosis phenotypes. For example, the C-C chemokine receptor 2 (CCR2) haplotype 2 has been linked to Löfgren's syndrome.³² In this study, the association between CCR2 haplotype 2 and Löfgren's syndrome remained significant even after adjustment for the presence of DRB1*03.³²

Ongoing genome-wide association studies (GWASs) are seeking to identify additional genes that may be linked to sarcoidosis onset and susceptibility. To date, these studies have identified several novel gene candidates.³³ In family clusters with sarcoidosis, GWASs have identified areas of interest in a German population.³⁴ A similar analysis of African-American familial sarcoidosis did not have identical findings but did find the same linkage at chromosomes 1p and 9q.³⁵

DIAGNOSING SARCOIDOSIS

The diagnosis of musculoskeletal disease related to sarcoidosis must be examined on the basis of two different presentations. The first is a patient with known sarcoidosis who presents with musculoskeletal complaints. The other is a patient with musculoskeletal disease in whom sarcoidosis is a possibility. Although the evaluations may be similar, crucial differences in approach are required.

One can never be sure of the diagnosis of sarcoidosis. The American Thoracic Society (ATS), the European Respiratory Society (ERS), and the World Association of Sarcoidosis and Other Granulomatous Disorders (WASOG) have developed diagnostic criteria. The patient with appropriate clinical presentation and multiple organ involvement who has granulomas identified in one or more organs, and who has no other cause for the granulomatous reaction, is considered to have sarcoidosis.¹ Figure 117-1 presents some features consistent with the disease.³⁶ Diagnosis relies

Figure 117-1 Various manifestations of sarcoidosis. **A**, Bilateral hilar adenopathy and right paratracheal lymph node enlargement demonstrated on a posterior anterior chest roentgenogram, Scadding stage 1.³⁸ **B**, Facial lesion consistent with lupus pernio.⁶⁰ **C**, Hand changes consistent with sarcoidosis in the fingers. **D**, Noncontrast magnetic resonance image of the pelvis demonstrating bone marrow replacement by granulomatous tissue. **E**, Cystic changes (arrows) within the bones of the fingers of a patient with sarcoidosis. **F**, Gadolinium enhancement of lesions of the spine seen on magnetic resonance image of a sarcoidosis patient. (**B**, Reproduced with permission from the patient.)

Table 117-1 Major Causes of Granulomatous Reaction besides Sarcoidosis

Infection	Environmental	Miscellaneous
<i>Mycobacterium tuberculosis</i>	Berylliosis	ANCA-associated vasculitis
Fungal	Hard metal	Necrotizing sarcoid granuloma
<i>Mycoplasma pneumoniae</i>	Zirconium	Lymphoma
<i>Pneumocystis jirovecii</i>	Tattoo	Cancer
Brucellosis	Hypersensitivity pneumonitis	Granulomatous lesions of unknown significance
Cat-scratch fever	Drugs (e.g., methotrexate)	Crohn's disease
Atypical mycobacteria		Lymphocytic interstitial pneumonia
Toxoplasmosis		Behçet's disease
		Rheumatoid nodules

ANCA, antineutrophil cytoplasm antibody.

Adapted from American Thoracic Society: Statement on sarcoidosis: joint statement of the American Thoracic Society (ATS), the European Respiratory Society (ERS) and the World Association of Sarcoidosis and Other Granulomatous Disorders (WASOG) adopted by the ATS Board of Directors and by the ERS Executive Committee, February 1999, *Am J Respir Crit Care Med* 160:736–755, 1999.

heavily on the finding of granulomas in the biopsy. However, many other conditions can lead to a granulomatous reaction, as is summarized in Table 117-1. Although sarcoidosis granulomas tend to be noncaseating and non-necrotizing, a significant number of sarcoidosis patients exhibit evidence of some necrosis in part of their granulomatous response. Certain features such as erythema nodosum, BHL, gallium scan showing increased activity in the parotids and lacrimal glands, an elevated angiotensin-converting enzyme (ACE) level, and bronchoalveolar lavage with increased lymphocytes with a CD4/CD8 ratio greater than 3.5 are strongly suggestive of sarcoidosis, even in a patient in whom a biopsy has not been performed.

The heterogeneity of the disease leads to varied clinical presentations, which may result in delayed diagnosis. One study of 189 patients with sarcoidosis found that only 15.3% of patients receive a diagnosis during their first visit to a physician.³⁷ Moreover, sarcoidosis can affect any organ, and this may cause a patient to be referred to a specialist who may not commonly manage sarcoidosis.³⁷ Complicating

further the diagnosis of sarcoidosis is its similarity of presentation to or concurrent existence with a variety of other conditions, most notably autoimmune disorders. Thus, sarcoidosis sometimes is diagnosed after other potential diagnoses have been excluded.

For the patient who presents with musculoskeletal disease and possible sarcoidosis, a vigilant approach is mandatory. A comprehensive multisystem evaluation as is commonly performed in rheumatology practice should prove informative. Table 117-2 lists some of the common manifestations that support or refute the diagnosis. For example, hilar adenopathy on a posterior chest roentgenogram is seen in about two-thirds of patients. Scadding proposed a staging system of the chest roentgenogram³⁸: stage 1 disease consists of hilar adenopathy alone (see Figure 117-1A); stage 2 disease is hilar adenopathy plus infiltrates; stage 3 is infiltrates alone; and stage 4 is fibrosis. Although this scoring is commonly used, differences may be noted in staging of the roentgenogram, even among sarcoidosis experts.³⁹ Patients may have evidence of pathology on chest computed tomography (CT) scan. Table 117-2 lists some less common features, which, when present, support the diagnosis.³⁶ These include erythema nodosum, lupus pernio (see Figure 117-1B), cranial seventh nerve paralysis, and hypercalcemia.

For patients with sarcoidosis, several tests (summarized in Table 117-3) have been proposed to serve as a minimal evaluation.⁴⁰ These tests reflect the fact that sarcoidosis is a multiple-organ disease, and one needs to look for evidence of specific organ involvement. Figure 117-1 demonstrates some of the features associated with sarcoidosis. Magnetic resonance imaging (MRI) with gadolinium may identify involvement of sarcoidosis in the brain⁴¹ or in the heart.⁴² MRI findings may also be useful in bone sarcoidosis or sarcoid arthritis.

Several lines of evidence have indicated that 18F-fluorodeoxyglucose positron-emission tomography (18F-FDG/PET) may be useful in extrapulmonary sarcoidosis, but it usually is not recommended as a first diagnostic tool. 18F-FDG/PET can be used to determine which organs are affected, particularly when no evidence of lung involvement is found. This includes cardiac sarcoidosis.⁴² Furthermore, this test can point investigators to appropriate organs

Table 117-2 Features Characteristic of Sarcoidosis

	More Likely Sarcoidosis	Less Likely Sarcoidosis
Chest roentgenogram	Bilateral hilar adenopathy	Pleural effusion
Computed tomography of chest	Upper lobe disease	
	Subpleural reticulonodular infiltrates	Subpleural honeycombing
	Mediastinal adenopathy	
	Peribronchial thickening	
Skin lesions	Traction bronchiectasis of upper lobe	
	Erythema nodosum	
	Lupus pernio	
	Maculopapular lesions	
Ocular disease	Uveitis	Episcleritis
	Optic neuritis	
Neurologic disease	Cranial seventh nerve paralysis	
Renal disease	Nephrocalcinosis	
Laboratory data	Elevated angiotensin-converting enzyme	Positive antineutrophil cytoplasm antibody
	Elevated serum calcium	
	Elevated alkaline phosphatase	

Table 117-3 Evaluation of Patient with Sarcoidosis

Initial Evaluation Suggested for All Patients
History, including occupational and environmental exposures
Physical examination
Posterior-anterior chest roentgenogram
Spirometry
Complete blood count
Liver function studies and serum calcium
Routine ophthalmic examination
Evaluation Considered in Selected Patients
Computed tomography scan of chest
Holter monitor and/or electrocardiogram
Urine analysis
Diffusion capacity of lung of carbon monoxide
X-ray of involved joints and/or ultrasound/magnetic resonance imaging
Follow-up Every 6-12 Months
Any abnormality noted on initial evaluation
Chest roentgenogram
Liver function studies and serum calcium
Spirometry

Modified from American Thoracic Society: Statement on sarcoidosis: joint statement of the American Thoracic Society (ATS), the European Respiratory Society (ERS) and the World Association of Sarcoidosis and Other Granulomatous Disorders (WASOG) adopted by the ATS Board of Directors and by the ERS Executive Committee, February 1999, *Am J Respir Crit Care Med* 160:736–755, 1999.

to biopsy when no distinct organ system involvement is obvious.⁴³

Criteria for specific organ involvement in patients with known sarcoidosis have been proposed.⁴⁴ Definitive organ involvement may be obvious or can be established by a positive granuloma biopsy from the affected tissue. For example, it is possible that arthritis with no other cause may be attributed to underlying sarcoidosis. However, patients with phalangeal cystic changes almost definitely can consider their arthritis to be a manifestation of their sarcoidosis⁴⁴ (Table 117-4).

Sarcoid Arthritis

Between 15% and 25% of patients with sarcoidosis have arthritis, which is the most frequently observed rheumatologic symptom of sarcoidosis. In patients with sarcoidosis, arthritis can be acute or chronic; the acute form is most common. Chronic arthritis is typically associated with multisystem sarcoidosis.⁴⁵

Acute Sarcoid Arthritis

Febrile arthropathy is the most frequently observed joint involvement in sarcoidosis. Although any joint may be involved, the condition usually is symmetric, involving ankles, knees, wrists, and elbows, and exists with BHL and erythema nodosum. Patients with acute sarcoid arthritis exhibit pain and stiffness, and their joints may be swollen or tender (Supplemental Figure 117-1 on www.expertconsult.com). Acute sarcoid arthritis sometimes resolves within weeks of onset, but occasionally symptoms last for several months. Once it resolves, this condition usually does not recur.

In a study of patients with acute sarcoid arthritis, Visser and colleagues prospectively evaluated patients and published criteria to assist in diagnosis.⁴⁵ Of 579 participants, 55 (9%) patients were eventually diagnosed with sarcoid arthritis. Diagnoses were made after it was established that patients had a combination of arthritis and BHL, as determined by chest radiography. From the findings of their study, investigators established criteria with 93% sensitivity and 99% specificity to guide physicians in differentiating between sarcoid and other causes of arthritis. Of the following criteria, patients must have three out of four characteristics to establish a diagnosis of sarcoid arthritis: younger than 40 years of age, EN, symmetric ankle arthritis, and symptoms lasting less than 2 months.⁴⁵

In addition to Visser's criteria, most symptoms of sarcoid arthritis vary among patients. Patients with sarcoid arthritis frequently have elevated erythrocyte sedimentation rates,^{45,46} but other symptoms, such as fever, are observed only in up to 66% of patients.^{45,48} Of note, a small minority of patients with acute sarcoid arthritis may develop abnormal alterations in their bones that can be seen on radiographs of the hands or feet. In some patients, sarcoid dactylitis may be the presenting symptom (see Figure 117-1C and E), characterized by swollen soft tissues surrounding affected fingers, erythematous skin, or tenderness. Individuals with dactylitis may also have nail abnormalities, such as dystrophy. Therefore, it is important to rule out other conditions that affect the nails, such as psoriatic arthritis, when making sarcoid arthritis diagnoses.

Other bone areas that may be affected by sarcoidosis include nasal bones, pelvic girdle structures, ribs, and skull. Patients with lupus pernio may be particularly at risk for developing abnormalities in their nasal bones. Because of similarities between a patient with sarcoidosis who has nasal bone involvement and a patient with granulomatosis with polyangiitis (GPA) (formerly Wegener's granulomatosis), it is important to distinguish between these conditions.⁴⁹ Serology may be useful because most patients with GPA will have a positive antineutrophil cytoplasm antibody (ANCA), but sarcoidosis does not lead to a positive ANCA.⁵⁰ On the other hand, about 60% of sarcoidosis patients will have an elevated ACE level at presentation; this is not seen in the presence of vasculitis.⁴⁹ Lesions in the pelvic bones (see Figure 117-1D) or in the spine (see Figure 117-1F) may, at first, lead one to suspect cancer metastases. Therefore, a comprehensive assessment is warranted in patients who present with changes in their skeletal bones, even if they exhibit other symptoms reminiscent of sarcoidosis.

Chronic Sarcoid Arthritis

The chronic form of sarcoid arthritis is less common than the acute form, and it affects more African-American than Caucasian individuals. It most often affects individuals with systemic sarcoidosis and multiorgan involvement. In some patients, joint symptoms manifest early in the course of sarcoidosis, whereas other patients develop sarcoid arthritis several years after onset of the disorder. Lupus pernio and chronic uveitis may manifest concomitantly with the chronic form of arthritis.

As is the case with other organ system manifestations, several conditions may mimic sarcoid arthritis and should

Table 117-4 Features Comparing Sarcoidosis with Other Rheumatologic Diseases

	Sarcoidosis	SLE	RA	PsA	Systemic Vasculitis
Clinical Findings	Lungs, eyes, and skin most common; any other organ (heart, brain, skin, bone, liver, etc.) may also be affected	Joints, kidneys (nephritis), mucous membranes, circulatory system, nervous system, lymph nodes, spleen	Joints (most common), lungs, blood vessels	Joints (oligoarthritis, polyarthritis), skin (psoriatic lesions), nails (dystrophy, dactylitis)	Blood vessels (wall thickening), skin (purpura, infarct ulcers), nervous system (headache, meningitis, seizures), joints (arthritis), kidneys (hypertension), heart, GI system
Radiographic Findings	Bilateral and mediastinal hilar adenopathy, reticulonodular opacities	Bilateral, diffuse air space opacity; diaphragm elevation ("shrinking lung syndrome")	Joint space narrowing, joint erosions, inflammation	Joint space narrowing, erosions, ossification near joints	Granulomatous lesions; multiple bilateral nodules; patchy areas of consolidation
Pathologic Findings	Noncaseating granulomas	Inflammation, blood vessel abnormalities such as vasculitis, immune complex deposits	Swollen synovium; presence of fibroblast-like and macrophage-like synoviocytes, macrophages, T and B cells	Increased synovial vascularity, dilated blood vessels, neutrophil infiltration	ANCA staining pattern on neutrophils and monocytes; patchy infiltrates, vessel wall granulomas, fibrous tissue
Laboratory Findings	Elevated ACE; hypercalcemia; presence of ANAs, ANCAs, and anti-dsDNA	Anti-dsDNA, anti-Smith, ANAs, RNP, antithrombin, anti-Ro/SSA, anti-La/SSB, anti-topoisomerase, aPL	Rheumatoid factor, ACPA, aPL	ANA (common), anti-dsDNA, rheumatoid factor, anti-Ro, anti-RNP (rare), aPL	ANCA, aPL, inflammatory markers (CRP)
MCTD	Scleroderma	Antiphospholipid Syndrome	Sjögren's Syndrome	Ankylosing Spondylitis	Reactive Arthritis
Raynaud's phenomenon; joints, muscles, lungs, heart, kidneys, and nervous system may be affected	Skin (tightening, thickening, induration), joints, GI system, lung, heart, kidney	Blood vessels (arterial/venous thrombosis, thrombocytopenia, fetal loss)	Eyes, mouth, and mucous membrane dryness; joints (arthritis), skin, kidneys, nervous system, lymph nodes may be affected	Vertebral arthritis, back pain, stiffness, synovitis, peripheral arthritis, pulmonary symptoms, iritis	Arthritis, conjunctivitis; urethritis; usually following genitourinary or gastrointestinal infection
Diffuse periarticular osteopenia; swelling of soft tissue; joint erosions, joint space narrowing, tuft resorption, and soft tissue atrophy	Pulmonary fibrosis, diffuse reticulonodular pattern	Patchy infiltrates	Mild joint space narrowing	Vertebral inflammation; sacroiliitis; bone erosions, syndesmophytes	Proliferation at tendon insertion; sacroiliitis; syndesmophytes
Autoantigen modifications, B and T cell activation	Excess matrix deposition, fibrosis; endothelial cell dysfunction and death; destruction of small vessels	Structural glomerular changes	B cell infiltration	Capsular fibrosis; ossification	Bacterial infection (<i>Shigella</i> , <i>Salmonella</i> , <i>Campylobacter</i>)
ANA, RNP, aPL	ANA (anti-topoisomerase), aPL, ACAs	Lupus anticoagulant, aPL, anti-protein C, anti-prothrombin, anti-protein S, anti-annexin	ANA, anti-Ro/SSA, rheumatoid factor, aPL	Elevated ESR, leukocytosis, HLA-B27	ANCA, HLA-B27; elevated ESR, CRP

ACA, anticardiolipin antibody; ACE, angiotensin-converting enzyme; ACPA, anticitrullinated protein antibody; ANA, antinuclear antibody; ANCA, antineutrophil cytoplasm antibody; aPL, antiphospholipid antibody; CRP, C-reactive protein; dsDNA, double-stranded DNA; ESR, erythrocyte sedimentation rate; GI, gastrointestinal; MCTD, mixed connective tissue disease; PsA, prostate-specific antigen; RA, rheumatoid arthritis; RNP, ribonucleotide protein; SLE, systemic lupus erythematosus; TNF, tumor necrosis factor.

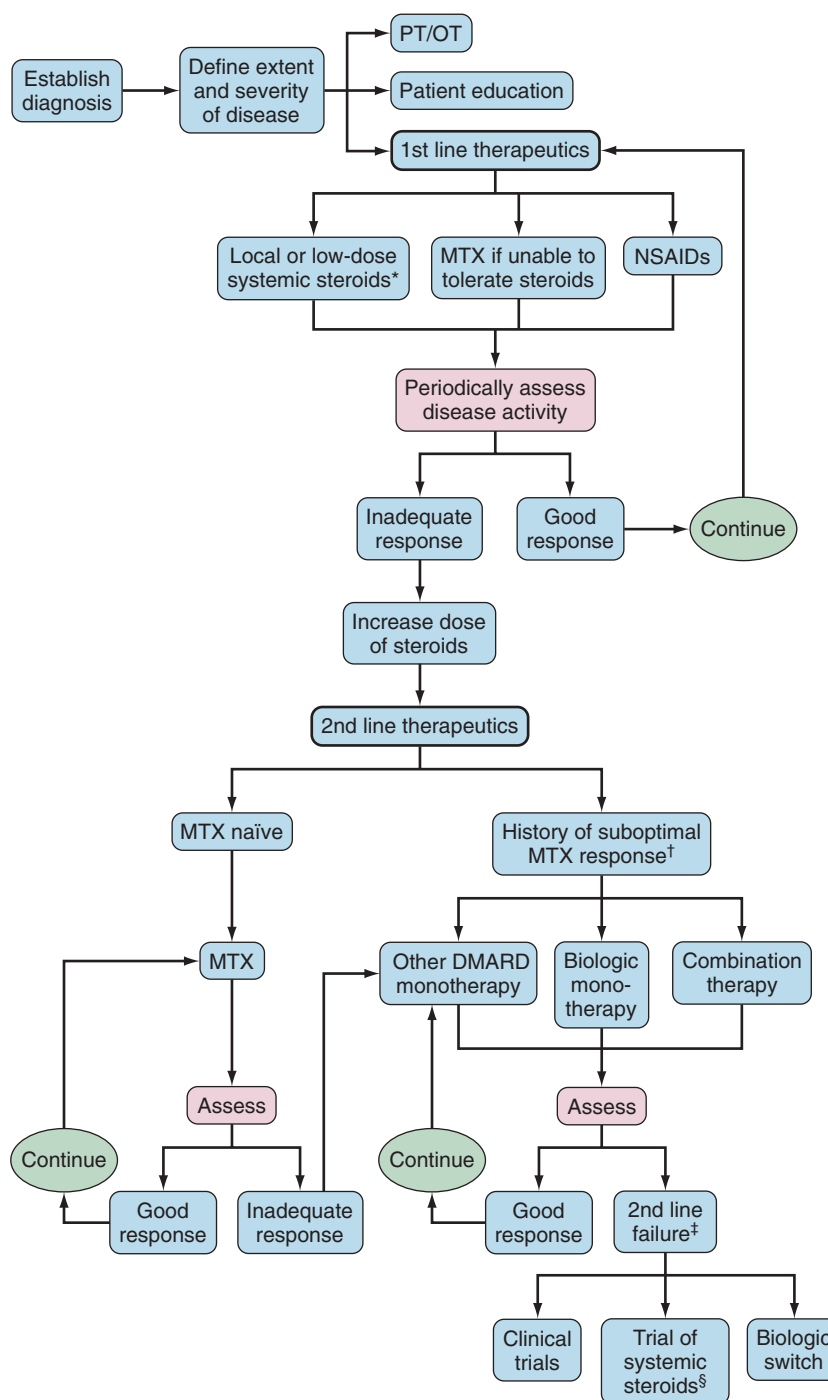

Figure 117-2 Algorithm describing an approach to treating sarcoidosis arthritis. *, Low dose steroids: <10 to 20 mg prednisone daily. †, Suboptimal response to MTX: intolerance to drug, lack of satisfactory efficacy on dosage up to 25 mg/wk, or a contraindication to medication use. ‡, DMARD failure: progressive disease or drug intolerance. §, Methylprednisone preferred over prednisone if prednisone has been used previously. DMARD, disease-modifying antirheumatic drug; MTX, methotrexate; NSAIDs, nonsteroidal anti-inflammatory drugs; OT, occupational therapy; PT, physical therapy. be excluded. For example, symmetric oligoarthritis or polyarthritis and an elevated rheumatoid factor are common features of sarcoid arthritis, but they may also result from reactive arthritis or rheumatoid arthritis (RA). Furthermore, a subset of patients with RA may develop some lung dysfunction, which can cause confusion in differentiating RA from sarcoidosis. In addition, some patients with RA have been reported to eventually develop coincident sarcoidosis, although sarcoidosis coexisting with connective disease disorders is rare. Therefore, it is crucial for physicians to distinguish between the two conditions, or to determine whether the two diseases are comorbid within the same patient.

In patients with migratory polyarthritis, rheumatic fever may be suspected, particularly when joint symptoms manifest before additional sarcoidosis-related symptoms are noted. A biopsy of the synovium or tendon sheaths may be helpful with characteristic granulomas appearing at pathology. Differential diagnoses for patients with monoarthritis include gout, septic arthritis, and calcium pyrophosphate dihydrate (CPPD)-positive arthritis (see [Tables 117-3, 117-4](#), and supportive content for detailed consideration of the diagnostic approach).²

MANAGING SARCROIDOSIS: FOCUSING ON SARCOID ARTHRITIS

No treatments have been U.S. Food and Drug Administration (FDA)-approved for sarcoidosis or for any of its manifestations, including sarcoid arthritis. Furthermore, no randomized trials have been conducted that can guide clinical decision making. To help guide clinicians in management, we have proposed a treatment algorithm, which is shown in [Figure 117-2](#).² Nonsteroidal anti-inflammatory drugs, methotrexate, and local or low-dose systemic corticosteroids are our preferred first-line therapies. Alternatively, hydroxychloroquine may be used. Using information obtained from the diagnostic evaluation, the clinician usually makes treatment decisions after carefully considering the disease severity and its probable clinical course, as revealed by its radiographic progression.

The proposed algorithm requires regular patient visits to monitor disease activity and therapeutic efficacy and tolerability. Responders remain on first-line agents until disease resolution or, alternatively, treatment failure. Before nonresponders are prescribed second-line therapies, higher doses of corticosteroids may be used, depending on tolerability and manifest toxicity. If patients do require second-line medications, two options are available: (1) methotrexate may be given to methotrexate-naïve patients, or (2) biologic therapies consisting of nonmethotrexate disease-modifying antirheumatic drugs (e.g., sulfasalazine, hydroxychloroquine, azathioprine), monotherapy, or combinations thereof may be prescribed to patients who inadequately respond to first-line methotrexate.

For patients for whom this treatment approach fails, one can consider an alternative biologic therapy or an aggressive course of systemic corticosteroids with careful toxicity monitoring. Alternatively, participating in a clinical trial may be appropriate for some patients.

Vitamin D metabolism represents a complex issue in sarcoidosis. Up to 10% of sarcoidosis patients will have

hypercalcemia or hypercalciuria.⁵² The mechanism usually attributed has been increased production of 1,25-dihydroxyvitamin D (1,25-OH₂D) by epithelioid cells in the granuloma. In one study, elevated 1,25-OH₂D was associated with prolonged need for treatment.⁵³ However, this same group of patients often requires treatment for osteoporosis.⁵⁴ Bisphosphonates alone may be adequate to treat corticosteroid-induced osteoporosis.⁵⁵ Because of the disassociation between 25-hydroxyvitamin D (25-OHD) and 1,25-OH₂D in sarcoidosis, it seems reasonable to measure both levels to ascertain which patients should receive vitamin D supplements.

Future Directions

Much remains to be learned about sarcoidosis. Its causes remain unclear, and no medications have been FDA-approved for its treatment. Although increasing attention has been paid to the underlying mechanisms of granuloma formation, full details of sarcoidosis immunopathogenesis have yet to be determined. Appropriate animal models and candidate genes are needed to help advance our understanding of this disease.

Large clinical trials are warranted. We have presented an algorithm for use in treating patients with an established diagnosis of sarcoidosis. However, treatment approaches vary by institution and by individual clinician owing to a myriad of conflicting studies that have been published about sarcoidosis management. Furthermore, therapeutic choices will likely differ according to the type and extent of organ system involvement observed in individual patients.

For relapsed and refractory disease, steroid-sparing agents including cytotoxic drugs and novel biologic therapies such as anti-TNF treatments have been used increasingly. Anti-TNF agents have been investigated in numerous sarcoidosis studies because of the potential role of TNF and other proinflammatory factors in sarcoidosis pathogenesis. Limiting their usefulness in this setting are mounting reports of granulomatous reactions to anti-TNF therapies in patients treated with these agents for nonsarcoidosis indications. Simply put, TNF inhibitors may help treat and may cause sarcoidosis.⁵⁶⁻⁵⁹ With this point in mind, it is relevant to our discussion that the presentation of anti-TNF-induced sarcoidosis, similar to all phenotypes of sarcoidosis, is a unique entity, but it does overlap with that of other autoimmune diseases. Furthermore, anti-TNF agents have been reported to induce autoimmune diseases other than sarcoidosis, including systemic lupus erythematosus (SLE), vasculitis, and interstitial lung disease. Diagnosing these conditions in patients with anti-TNF-induced sequelae is critical.

**KEY POINTS**

Elevated ferritin (>200 µg/L) and transferrin saturation (>45%) in the absence of other causes are useful screening measures for hereditary hemochromatosis (HHC).

Genetic testing should be reserved for patients with suggestive biochemical abnormalities or a positive family history of HHC or both.

Disease phenotype varies greatly among individuals with similar genotypes of the key gene associated with this disease, including genes encoding HFE, hepcidin, hemojuvelin transferrin receptor 2, and ferroportin.

Diet, alcohol intake, and other risk factors for chronic liver disease all influence the clinical expression of HHC.

Phlebotomy is an effective treatment for decreasing iron stores.

Some clinical manifestations of disease improve with treatment (constitutional symptoms, diabetes mellitus, liver enzyme abnormalities), whereas others are unaltered (arthritis, hypogonadism, cirrhosis).

Atypical osteoarthritis or chondrocalcinosis should trigger a search for an underlying metabolic disorder.

The earlier the diagnosis, the better is the prognosis.

Hemochromatosis refers to the presence of excess iron in body tissues because of increased iron absorption. Primary or hereditary hemochromatosis (HHC) is an autosomal recessive disease, whereas *secondary hemochromatosis* refers to iron overload as a result of increased iron availability, ineffective erythropoiesis, or inherited abnormalities of iron metabolism.

Hemochromatosis was first recognized in the 1880s in a series of case reports that described “bronze diabetes” and “pigmented cirrhosis,” but von Recklinghausen is credited with the first use of the term in 1889.¹ In 1935, the familial pattern of HHC was described by Sheldon,² who suggested that the disease was due to an inborn error of metabolism. Finch and Finch in 1955³ showed that HHC was caused by abnormal iron absorption in the presence of a normal diet. At that time, premorbid recognition of the problem was uncommon, however, and most cases were diagnosed at autopsy. In 1972, serum ferritin became available as a measure of iron stores. Three years later, Simon and colleagues⁴ discovered that the HHC gene was present on chromosome 6, close to the HLA-A locus. It took 21 more years for the mutated gene, *HFE*, to be described, and in the last decade, it has been recognized that other gene mutations also can cause iron overload.⁵ Genetic testing has

revolutionized the diagnosis of HHC, although the phenotype of any given mutation may vary greatly.^{6,7} Nevertheless, the detection of such genes has greatly enhanced the overall prognosis of this condition by allowing the disease to be diagnosed at a preclinical stage in high-risk individuals. This discovery has helped many patients with HHC achieve a normal life expectancy. Improved knowledge at a molecular level has further aided our understanding of the pathogenesis and therapeutic implications of hemochromatosis, permitting many patients with this disease to achieve a normal life expectancy.

NORMAL IRON METABOLISM

The average total body iron content in adults is 3 to 4 g, mostly contained within hemoglobin, but also present in myoglobin and cytochromes, in addition to the storage proteins ferritin and hemosiderin (Table 118-1). Of a typical daily Western diet of 10 to 20 mg of iron, 1 to 2 mg is absorbed by duodenal enterocytes each day.^{8,9} Heme dietary sources from fish and meat have a higher bioavailability than nonheme sources, such as vegetables. The addition of ascorbic acid to the meal increases absorption of nonheme iron, whereas tannins, bran, and phytates inhibit iron absorption.^{10,11}

Iron homeostasis is tightly controlled at cellular and molecular levels, influenced by numerous mechanisms, including recent dietary iron intake, the extent of iron stores in the body, and key regulatory peptides. Communication between sites of iron uptake (enterocytes), storage (liver and macrophages), and utilization (erythroid cells) is essential, and an antimicrobial peptide, hepcidin, plays a key role in this regard.¹² Hepatic synthesis of hepcidin is stimulated by increases in the body's iron requirements, as in situations of anemia, hypoxia, or inflammation.^{13,14} Hepcidin prevents iron loss by reducing the entry of iron into the bloodstream via inhibition of ferroportin, a membrane-bound iron exporter protein found on macrophages, hepatocytes, and enterocytes.^{14,15} Hepcidin production is downregulated when iron requirements return to normal. In the presence of normal iron stores, iron is retained in the intestinal cells by the protein, mobilferritin, and is subsequently excreted when these cells are shed.

When body iron stores reach an adequate level, ferritin production is increased to facilitate storage, and the transferrin receptor is downregulated to minimize the entry of iron into the cells. The iron responsive element binding protein mediates this process by detaching from ferritin mRNA so that more ferritin can be produced.¹⁶ With increasing iron stores, circulating transferrin becomes saturated, and iron is preferentially offloaded to tissue sites

Table 118-1 Definitions of Terms Used in Iron Metabolism

Term	Definitions
Ferritin	Major iron storage protein in iron storage diseases and inflammation Markedly increased in adult-onset Still's disease Plasma levels reflect iron stores (e.g., 1 ng/mL ferritin = 10 mg iron)
Transferrin	Transporter protein for iron in plasma Synthesized in liver Increased in iron deficiency states
Transferrin saturation	Serum iron ($\mu\text{g/dL}$) \div total iron-binding capacity ($\mu\text{g/dL}$) $\times 100$ in iron deficiency anemia/chronic disease/ferroportin mutation in hemochromatosis/ineffective erythropoiesis/iron overload states/severe liver failure
Iron regulatory proteins	Maintain iron homeostasis by modulating synthesis of transferrin receptors/ferritin/duodenal iron transporter
HFE protein	Identified in cells of deep crypts of duodenum and in Kupffer cells Modulates uptake of transferrin-bound iron into duodenal crypt cells
Iron exporter proteins	Ferroportin/hephaestin/divalent metal transporter 1 (DMT1)
Hepcidin	Acute phase reactant produced by liver Intrinsic antimicrobial activity Negative regulator of iron absorption Reduces iron release from macrophages Prevents iron loss by reducing entry of iron into bloodstream via inhibition of ferroportin Mutations found in some families with juvenile hereditary hemochromatosis
Hemojuvelin	Modulates hepcidin expression
Hemosiderin	Histologic identification of iron stain in tissues

that contain cells with high levels of transferrin receptors, such as liver, heart, thyroid, gonads, and pancreatic islet cells.¹⁷

GENETICS OF HEMOCHROMATOSIS

Four types of HHC have now been described, all linked to gene mutations (Table 118-2).^{18,19} Classic HHC (type 1) is

Table 118-2 Hereditary Hemochromatosis (HHC)

Name	Gene	Gene Product	Pattern of Inheritance
HFE-Related HHC			
Type 1	<i>HFE</i> , 6p21.3	HFE	Autosomal recessive
Juvenile-Type HHC			
Type 2A	<i>HJV</i> , 1q21	Hemojuvelin	Autosomal recessive
Type 2B	<i>HAMP</i> , 19q13.1	Hepcidin	
TfR2-Related HHC			
Type 3	<i>TfR2</i> , 7q22	Transferrin receptor 2	Autosomal recessive
Ferroportin-Related HHC			
Type 4	<i>SLC40A1</i> , 2q32	Ferroportin	Autosomal dominant

an autosomal recessive disorder, with a mutation of the *HFE* gene, located on chromosome 6 (*HFE*-related HHC). Although numerous such mutations have been described, the most common is a single amino acid substitution of tyrosine for cysteine at position 282 (C282Y). This particular mutation is thought to have arisen in a Celtic/Viking ancestor more than 2000 years ago and is now one of the most common genetic defects in individuals of Northern European origin. This anomaly had no reproductive implications, but may have had survival advantages by protecting against iron deficiency in a susceptible population. Homozygosity for this mutation is a risk factor for organ damage secondary to iron deposition, although phenotypic expression varies widely. Other mutations of the *HFE* gene include the replacement of histidine with aspartic acid at position 63 (H63D) and the substitution of serine for cysteine at position 65 (S65C). Clinical manifestations of the latter mutations seem to be less serious, although compound heterozygosity of such defects may be associated with evidence of iron overload.

Unlike mutations of the *HFE* gene that may become clinically obvious in middle age, hemojuvelin (*HJV*-related HHC, type 1A) or hepcidin (*HAMP*-related HHC, type 2B) mutations result in juvenile HHC (type 2), which may manifest in the teens or twenties. The rate of iron accumulation seems to be greater than in adult HHC and is often associated with widespread organ involvement and early mortality.²⁰ In contrast to the Northern European inheritance of *HFE* mutations, juvenile HHC has been most commonly reported in Italy.²¹ Clinical manifestations of transferrin receptor mutations (*TfR2*-related HHC, type 3) seem to resemble manifestations of the classic *HFE*-related HHC. Such mutations are rare, and few cases have been described.^{22,23}

Type 4 or ferroportin-related HHC is an autosomal dominant condition, described in European and Australian families.^{24,25} Two types of ferroportin mutations have been reported. In the first, loss of surface localization of ferroportin results in a decreased ability of cells to export iron, causing iron to build up predominantly in macrophages. In the second, hepcidin-induced ferroportin dysfunction leads to iron accumulation in parenchymal cells of the liver and other tissues. Phenotypic expression varies, with some patients manifesting the effects of iron overload in a similar manner to classic HHC, and others showing minimal evidence of organ damage.²⁶

EPIDEMIOLOGY

Although HHC previously was thought to be a rare condition, genetic testing has revealed that it is one of the most common heritable disorders. Although 5 out of every 1000 individuals of Northern European origin are homozygous for the *HFE* mutation, phenotypic expression varies, and clinical cases are much fewer in number. In a study of nearly 100,000 individuals from primary care practices in the United States, the prevalence of C282Y homozygosity was as follows: white, 0.44%; Native American, 0.11%; Hispanic, 0.027%; African-American, 0.014%; Pacific Islander, 0.012%; and Asian, 0.0004%.²⁷ Peak age at the time of diagnosis is 40 to 60 years for classic HHC.

PHENOTYPIC DISEASE EXPRESSION

Clinical manifestations of HHC vary greatly between individuals with similar mutations, suggesting that other factors influence disease expression. One study demonstrated that among C282Y homozygotes, up to 82% have hyperferritinemia, while approximately 28% of male and 1% of females ultimately develop clinical manifestations of HHC—defined as the presence of liver disease, hepatocellular carcinoma, and arthritis of the second and third metacarpophalangeal joints—by the age of 65.²⁸ In contrast, compound heterozygotes with C282Y/H63D mutations exhibit higher serum ferritin and transferrin saturation levels compared with normal controls, but are at very low risk of clinical HHC.²⁹

Other genes may play a role in modifying the phenotypic expression of iron overload. The presence of the gene *CYBRD1*, which encodes duodenal reductase DCYTB, has been shown to be associated with lower serum ferritin levels in C282Y homozygotes.³⁰ Furthermore, mutations of other iron-related genes, such as hepcidin, hemojuvelin, haptoglobin, and bone morphogenetic protein, may influence disease manifestations.^{31–35} In addition, profibrotic genes (e.g., TGF) may accelerate the onset of cirrhosis in susceptible individuals.³⁶

Why HHC disease penetrance is more evident in C282Y homozygote males than females may be explained by recurrent menstrual blood loss and consequent slower accumulation of iron stores in women. However, genetically determined sex differences in ferritin levels may occur, as distinct HLA A*03B*07 and A*03B*14 haplotypes have been reported in men and women with clinical evidence of HHC.³⁷

Environmental factors, including diet, smoking, alcohol intake, and comorbid diseases, also influence clinical expression of HHC. The metabolic syndrome is associated with insulin resistance–associated iron overload, which, in the presence of HHC, may have a synergistic effect on liver damage.¹⁴ Concurrent liver disease, due to hepatitis or steatosis, may exacerbate the process of fibrogenesis.³⁸ Excess alcohol, meat consumption, and high citrus fruit intake also contribute to increased iron loading. However, ingestion of noncitrus fruits may have a protective effect.³⁹

PATHOGENESIS

Hepcidin is a key regulatory peptide in the pathogenesis of HHC. Produced by the liver, it acts by binding to ferroportin on enterocytes and macrophages, thereby restricting dietary iron absorption from the gut and inhibiting release of iron recycled by macrophages from aging red cells.^{12,15} In HHC, inadequate hepcidin synthesis leads to increased intestinal iron absorption and the subsequent deposition of iron in tissues. Absence of hepcidin results in early, severe iron loading, and overexpression of this protein can significantly improve iron deposition in a mouse model of HHC.^{12,40–42}

Chronic iron overload is thought to cause tissue damage via several mechanisms, including weakening of lysosomal membranes and consequent discharge of enzymes into the cytoplasm. Increased free radical formation contributes to

lipid peroxidation of cell membranes. The extent and duration of iron deposition correlate with the development of fibrosis, and it is thought that substantial hepatocyte and Kupffer cell iron accumulation precedes organ damage.¹⁴ In HHC, iron first accumulates in parenchymal cells, with reticuloendothelial (RE) involvement a late feature, in contrast to transfusional iron overload, in which RE cells are primarily targeted. Values of serum ferritin exceeding 1000 µg/L are associated with significantly increased risks of liver fibrosis and cirrhosis.^{7,43}

CLINICAL FEATURES

Extra-articular Manifestations

HHC is more common in men than in women and typically manifests in middle-aged adults as iron stores gradually accumulate, often reaching 20 to 30 g. Organ involvement varies and is unpredictable, although the liver, as the major site of iron storage, is typically affected. Commonly, abnormalities of the liver enzymes, checked as part of a routine health screen, are the initial indication of disease. The degree of iron overload has a direct impact on the life expectancy of the affected individual. Without an early diagnosis, progressive fibrosis leading to cirrhosis may occur.^{44,45} The risk of hepatocellular carcinoma is greatly increased in patients with established cirrhosis.⁴⁶

Glucose intolerance tends to be a late finding in HHC and is due to progressive iron accumulation in pancreatic beta cells causing low C-peptide and insulin levels. Alpha cell function is usually preserved, however, and serum glucagon levels are normal or increased.⁴⁷ The risk of diabetes mellitus also is higher in C282Y heterozygotes with no clinical evidence of HHC compared with controls.⁴⁸

Iron deposition in the heart can result in conduction system abnormalities and heart failure. Several large population studies of HHC and atherosclerosis have failed to find a link. However, elevated ferritin levels, particularly in the setting of nonalcoholic fatty liver disease, may be associated with vascular damage via hepcidin upregulation.^{49–51}

Pituitary involvement in HHC is due to iron deposition, resulting in reduced serum levels of secreted hormones from this gland. Low levels of gonadotropic hormone cause loss of libido and erectile dysfunction.^{44,52} Hypothyroidism in HHC is thought to be due to a direct toxic effect of iron on thyroid cells and is associated with low thyroxine and elevated thyroid-stimulating hormone.⁵³ Such endocrine abnormalities may contribute to the development of osteoporosis in these individuals.

Skin discoloration occurs as a result of extra melanin and iron in the epidermis. It is a late finding, and the development of “bronze diabetes” represents the end stage of years of iron accumulation in the tissues.

Patients with HHC have increased susceptibility to certain infections. High serum iron concentrations may increase bacterial virulence, whereas excess iron in macrophages is thought to reduce phagocytosis.⁵⁴ Particular caution is advised with uncooked seafood because of the risk of septicemia from *Vibrio vulnificus*. In addition, *Yersinia enterocolitica*, *Listeria monocytogenes*, *Salmonella enteritidis* serotype typhimurium, *Klebsiella pneumoniae*, *Escherichia coli*,

Hemochromatosis arthropathy

Figure 118-1 A and B, Arthritis of the second and third metacarpophalangeal joints, characteristic of hereditary hemochromatosis.

Rhizopus arrhizus, and *Mucor* species all have been reported to cause severe illness in patients with iron overload.⁸

Apart from the increased risk of malignant hepatoma in patients with established cirrhosis is an independent association of nonhepatic cancers, particularly breast and colorectal tumors, in HFE C282Y homozygotes.⁵⁵ H63D homozygosity confers a threefold increased risk of colorectal cancer in carriers of the MMR gene mutation.⁵⁶ Iron is potentially carcinogenic via several mechanisms, including its immunosuppressive properties and its role as an essential cofactor for tumor cell growth and in catalyzing the formation of hydroxyl radicals.⁵⁵ Furthermore, cancer risk is lower with reduced iron stores.⁵⁷

Articular Features

Arthralgia/arthritis is a common presentation in HHC, affecting 50% to 80% of patients and significantly interfering with quality of life.⁵⁸⁻⁶³ Although it tends to be a late feature, joint pain may nevertheless be the presenting symptom of HHC, alerting a diligent physician to the presence of an underlying metabolic disorder. Articular involvement may be widespread, but changes to the second and third metacarpophalangeal joints are most characteristic⁶⁴ (Figures 118-1 and 118-2). Arthritis may be present in the proximal interphalangeal joints, wrists, shoulders, hips, knees, and ankles.⁶³ Patients notice pain and stiffness of the involved joints, but evidence of synovitis is usually absent. Hip damage develops in approximately 25% of individuals with HHC, and after hip arthroplasty, the risk of aseptic loosening of the prosthesis is increased.^{65,66} The differential diagnosis of HHC-related arthropathy includes severe osteoarthritis, rheumatoid arthritis, other forms of inflammatory arthritis, and crystal arthritis. Rheumatoid factor is typically negative, however, and radiographs, in established cases, show distinctive findings, such as joint space narrowing of the second and third metacarpophalangeal joints, hook-like osteophytes on the radial aspect of the metacarpal heads, and chondrocalcinosis, particularly of the triangular

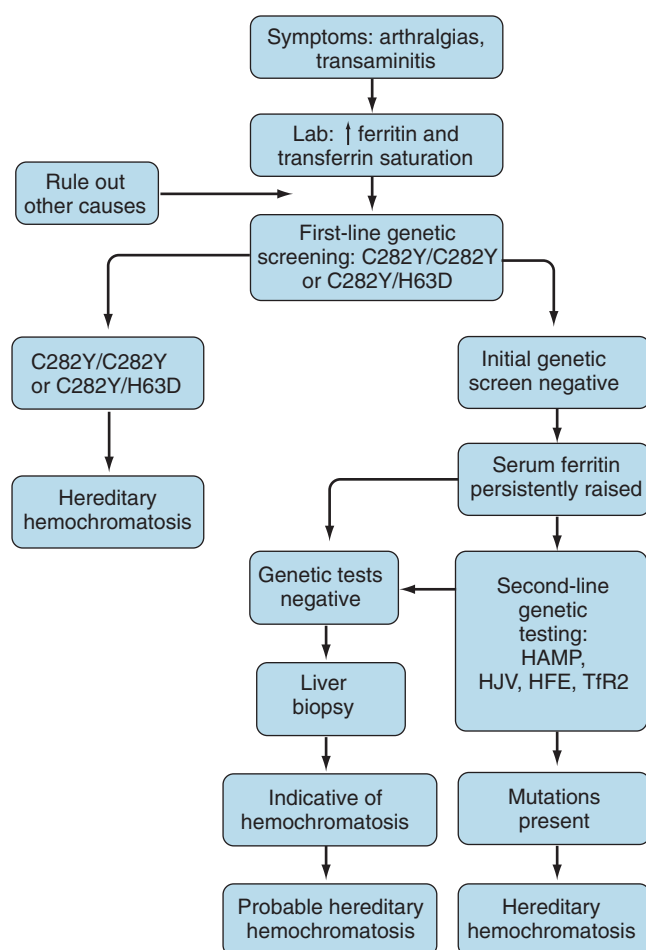

Figure 118-2 Algorithm for the diagnosis of hereditary hemochromatosis.

fibrocartilage adjacent to the ulnar styloid. HHC-related arthritis is more common in male C282Y homozygotes than in other genotypes.⁷

The pathogenetic mechanisms underlying HHC-related arthritis are unknown, and the prevalence of joint pain in this condition has not been found to correlate with body iron stores. Toxic effects from local iron deposition, acceleration of cartilage defects, and immunologic mechanisms have been implicated.^{60,61,67} Under light microscopy, the involved synovium demonstrates iron deposits, particularly in the lining cells, but inflammatory cell infiltration is not typical.⁶⁸⁻⁷⁰ Neutrophil infiltration of the synovial sublining layer has been described.⁷¹ Apatite and calcium pyrophosphate dihydrate crystals may be observed, but why they are preferentially expressed in HHC is unknown. In association with the increased incidence of calcium pyrophosphate dihydrate deposition disease in HHC, a putative role for a parathyroid hormone fragment (PTH 44-68) has been suggested.⁷²

DIFFERENTIAL DIAGNOSIS

Because no physiologic mechanism is in place to increase iron excretion, the inevitable result of increased iron entry into the body is iron overload. Excess iron may accumulate because of high intake of iron by oral or parenteral means. A full history of medication use, including over-the-counter iron tablets, and a review of any blood transfusions should be elicited. Ineffective erythropoiesis in conditions such as the thalassemias or sideroblastic anemia also results in the buildup of iron stores. Porphyria cutanea tarda is associated with hyperferritinemia, high transferrin saturation levels, and an increased incidence of *HFE* mutations.⁷³ However, the clinical findings, particularly dermatologic, distinguish this disease from HHC. Elevated ferritin levels may result from severe inflammation. Interleukin-6 is a potent stimulator of hepcidin via the STAT3 pathway, resulting in reduced iron absorption and elevation of tissue and serum ferritin levels.⁷⁴ However, these changes are accompanied by low transferrin saturation. Chronic liver disease resulting from hepatitis, alcohol excess, or fatty infiltration is associated with hyperferritinemia and normal or elevated transferrin saturation values. Alcohol, independent of liver damage, induces ferritin synthesis.^{46,75}

Genetic factors not related to HHC have been linked to other iron overload syndromes. The African iron overload syndrome occurs in a few Africans who drink locally brewed beer containing extremely high levels of iron (80 mg/L). Not all Africans who drink this beer develop hemochromatosis, leading to suggestions that additional genetic factors contribute to the development of disease. It is thought that a polymorphism of the ferroportin 1 gene is involved.⁷⁶ Separately, a familial association has been noted with a syndrome of very high ferritin levels (>1000 ng/mL) and bilateral congenital cataracts. This hereditary hyperferritinemia-cataract syndrome involves several mutations in the iron responsive element of L-ferritin and is inherited in an autosomal dominant fashion. The cataracts are thought to be due to excessive ferritin production within the lens fibers.⁷⁷

INVESTIGATIONS

A high index of suspicion is helpful when a patient presents with joint pain and abnormal liver enzymes. Although the differential diagnosis is wide, the presence of elevated ferritin and transferrin saturation levels (serum iron \times 100/total iron-binding capacity) strongly points to the answer. Serum iron should be measured with the patient fasting because concentrations may be increased after a meal.⁴⁴ High ferritin levels also may be caused by systemic inflammation or malignancy, but these conditions tend to be associated with reduced transferrin saturation. Other causes of elevated transferrin saturation include high serum iron secondary to hepatic cytolysis or low transferrin levels secondary to liver failure, and these possibilities should be excluded. If ferritin measures greater than 200 μ g/L, and transferrin saturation is greater than 45%, genetic screening is recommended.^{14,19,27} The finding of homozygosity for the C282Y mutation or compound heterozygosity for C282Y/H63D confirms the diagnosis.

Liver biopsy may be considered for prognostic purposes in established cases.^{6,18,44,78} HHC can be distinguished histologically from alcoholic cirrhosis by the preferential distribution of iron in the hepatocytes in the former and in the Kupffer cells in the latter.⁴⁴ Magnetic resonance imaging of the abdomen also can be used to determine iron overload in the internal organs. Gradient T2-weighted sequences show decreased signal intensity and correlate highly with liver iron concentrations. This imaging method also can identify other locations of iron deposition (e.g., in the spleen, pancreas, lymph nodes, and heart).^{44,79} Because HHC is a systemic condition, other investigations should include a search for diabetes, thyroid disease, hypogonadism, osteoporosis, and cardiomyopathy. Disease mimickers, such as porphyria cutanea tarda, ineffective erythropoiesis, and chronic alcohol excess, should be excluded.

SCREENING

Greater disease awareness and the availability of genetic screening have meant that HHC is increasingly likely to be diagnosed before the classic triad of cirrhosis, diabetes, and skin hyperpigmentation develops. Late presentation with evidence of end-organ damage does occur, however, particularly in patients with additional risk factors for iron overload or liver disease.

HHC is an attractive clinical target for population screening because of its high prevalence, potential disease severity, availability of effective treatment, and impact of early diagnosis on the morbidity and mortality of affected individuals. Certain groups are more at risk than others, however, and the disease prevalence is higher in white than in nonwhite individuals.^{6,7,27,80,81} Biochemical measures, such as serum ferritin, may serve as a cost-effective method of screening in whites during routine health checks and in individuals who complain of nonspecific symptoms, such as excessive fatigue and arthralgias. Elevation of serum ferritin in the absence of other causes should prompt measurement of transferrin saturation. Levels greater than 45% in men and greater than 35% in premenopausal women, without adequate explanation, warrant further investigation.

Genetic testing should be reserved for patients with suggestive biochemical abnormalities or a family history of HHC. Routine population screening for C282Y or H63D mutations is not recommended because of the variable clinical penetrance of these genes and the potential negative consequences of a positive result in asymptomatic patients, such as financial, legal, insurance, and psychological implications.¹⁹ When a case of HHC is diagnosed, however, and two gene mutations are identified (i.e., C282Y/C282Y or C282Y/H63D), siblings also should be tested for these mutations. H63D/H63D homozygotes are not thought to be at risk of clinical disease. Children of a patient with HHC or of an individual with C282Y/H63D heterozygosity are at risk only if the other parent also carries hemochromatosis gene mutations.

For individuals in whom genetic testing has identified a risk of HHC, but with no clinical evidence of disease, yearly biochemical screening should be done, with measures of ferritin, transferrin saturation, and liver enzymes. Such monitoring allows early detection of organ compromise and timely initiation of treatment (see Figure 118-2).

MANAGEMENT

Removing excess iron before the development of organ damage significantly abrogates the adverse consequences of HHC. Target groups for treatment include asymptomatic individuals with biochemical evidence of high iron stores, in addition to patients with overt clinical disease. Some features of HHC improve with bloodletting, including constitutional symptoms, diabetes, and liver enzyme abnormalities. Phlebotomy has no effect, however, on arthritis, hypogonadism, and liver fibrosis.¹⁸ When cirrhosis is established, the risk of hepatocellular carcinoma is greatly increased, even after a satisfactory reduction in iron stores.^{18,46}

Phlebotomy is an effective method of removing excess iron. The use of chelating agents is rarely necessary. Every 500 mL of whole blood contains 200 to 250 mg of iron, depending on the hematocrit. Phlebotomy can be arranged once or twice weekly, as tolerated by the patient, aiming for serum ferritin of 50 ng/mL. It can take longer than 1 year for iron stores to normalize with this regimen. Iron deficiency anemia should always be avoided, and when ferritin levels reach their target, the frequency of bloodletting may be reduced. Transferrin saturation levels are not an accurate measure of therapeutic efficacy because they are relatively resistant to changes in iron stores in C282Y homozygotes.¹⁴ Phlebotomy continues for life, and the maintenance schedule depends on the patient's ability to sustain the ferritin level in the low-normal range. It is important to avoid very low ferritin levels because this situation may increase iron absorption via further reduction in hepcidin levels or increased erythropoiesis in C282Y homozygotes.¹⁴ Blood removal in HHC is not without risks. In particular, life-threatening cardiac arrhythmias may develop during rapid mobilization of iron stores. Vitamin C supplementation may precipitate such problems by facilitating iron release and increasing pro-oxidant and free radical activity.¹⁸ Patients undergoing phlebotomy for HHC should not take extra vitamin C, but can continue to eat fresh produce containing this vitamin.

Other dietary recommendations include reduction or avoidance of food containing high doses of iron, such as red meat and internal organs. Uncooked shellfish is a particular hazard because of the risk of contamination with *V. vulnificus*. Some alcoholic drinks contain iron, and all are potentially hepatotoxic. Alcohol should be consumed only occasionally because it seems to have a synergistic effect in the presence of iron overload on the development of cirrhosis and hepatocellular carcinoma.^{82,83} Maintenance of normal body weight is important to avoid the hepatic damage associated with steatosis.³⁸

Just as the pathogenesis of joint pain in HHC is unclear, treatment of arthritis in this condition is unsatisfactory, and joint symptoms may progress despite effective phlebotomy. Nonsteroidal anti-inflammatory drugs, colchicine, and intra-articular corticosteroids may be helpful in some cases. Osteoporosis is a potential disease complication, particularly in the setting of hypogonadism or reduced thyroid function. Hormone replacement, if indicated, should be instituted, although some patients may require additional treatment with calcium and bisphosphonates. Screening for malignancy, particularly for carcinoma of the breast and colon, should be considered in the holistic care of patients with HHC.

OUTCOME

The earlier HHC is diagnosed, the better the prognosis, because morbidity and mortality are directly related to the extent of iron overload and consequent organ damage. The development of cirrhosis is a serious indicator of reduced longevity. For patients with HHC-related hepatic failure who undergo liver transplantation, survival rates are lower compared with individuals who receive liver transplants for other reasons. Postoperative death in these circumstances is typically due to cardiac complications or infection.^{18,84}

In the absence of cirrhosis or diabetes, patients with HHC have a normal life expectancy. Given the importance of timely recognition of this common metabolic problem, a vigilant physician can make an enormous difference in the lives of patients who present with early symptoms of this disease. In this context, the rheumatologist has a particularly relevant role in keeping a high index of suspicion for the diagnosis of HHC in patients with atypical osteoarthritis or chondrocalcinosis.

Future Directions

Cost-effective screening focused on those at greatest risk of clinical disease, in association with a high level of diagnostic suspicion in patients with relevant symptoms and signs, should reduce the number of patients presenting with irreversible organ damage from HHC. In addition, greater understanding of the genetic and environmental modifiers of clinical disease expression may help to delay or mitigate the consequences of iron overload in susceptible individuals. How comorbid disease influences the onset and extent of disease is particularly relevant in the context of the growing numbers of patients with obesity, metabolic syndrome, and hepatic steatosis. Although phlebotomy has been the mainstay of treatment for many years, exact targets for iron stores

and ferritin levels warrant further investigation. Other commonly used medications, such as proton pump inhibitors, which inhibit absorption of nonheme iron, or calcium channel blockers, which may have a role in reducing iron overload via divalent metal transporter-1, have a potentially therapeutic benefit in HHC.^{85,86} Currently at the experimental stage is the concept of hepcidin peptides or hepcidin agonists, aimed at correcting the physiologic deficit linked to increased iron absorption and deposition.¹²

Hemophilic Arthropathy

KATHERINE S. UPCHURCH •
DOREEN B. BRETTLER

KEY POINTS

Severe hemophilia, if not aggressively treated, is often complicated by recurrent hemarthrosis.

Recurrent hemarthrosis causes chronic arthropathy with overlapping clinical and pathologic features of osteoarthritis and rheumatoid arthritis.

Septic arthritis should be considered in hemophilic patients with risk factors (previous arthrocentesis, intravenous drug use, human immunodeficiency virus infection) and acute monoarticular arthritis.

Soft tissue and muscle hemorrhage are frequent complications of hemophilia.

With continuous factor infusion, surgical procedures, including total joint replacements, can be done safely in hemophilic patients.

The best treatment for hemophilic arthropathy is prevention of recurrent hemarthrosis through regular prophylactic factor replacement.

Although spontaneous joint hemorrhage has been described in a variety of inherited disorders of coagulation¹⁻³ and in the setting of anticoagulation therapy,⁴ it occurs most frequently in hemophilia. Bleeding into the joints is the complication of hemophilia that most often requires therapeutic intervention and, when it is recurrent, can lead to chronic, deforming arthritis that is independent of bleeding episodes.

Hemophilia refers to a group of inherited diseases characterized by functional deficiency of a specific clotting factor. The most common are hemophilia A (classic hemophilia) and hemophilia B (Christmas disease); the deficient factors are factor VIII (hemophilia A) and factor IX (hemophilia B). The incidence and severity of hemorrhagic complications of hemophilia are directly related to the severity of the underlying coagulation defect.

Although the intrinsic pathway of coagulation is severely impaired in hemophilia, the extrinsic tissue-dependent pathway remains intact and is probably the major hemostatic regulatory system. Normal synovial tissue and cultures of synovial fibroblasts have been found to be deficient in tissue factor,⁵ which suggests that in synovium-lined joints, hemophiliacs have functional inactivity of intrinsic and extrinsic coagulation pathways. This observation may explain the marked propensity toward hemorrhage in joints compared with other tissue sites in these patients.

CLINICAL FEATURES

The spectrum of articular disease in hemophilic patients has been the subject of numerous comprehensive reviews⁶⁻¹⁰ and includes acute hemarthrosis, subacute or chronic arthritis, and end-stage hemophilic arthropathy. The usual distribution of joint involvement is shown in [Figure 119-1](#). Involvement of the small joints of the hands and feet also may occur, although infrequently.

Acute Hemarthrosis

Nearly all patients with severe hemophilia A or B (<1% activity of the deficient factor) and half of patients with moderate disease activity experience hemarthrosis. Acute hemarthroses generally first occur when a child begins to walk, and they continue, usually cyclically, into adulthood, when the frequency diminishes. Patients frequently have premonitory symptoms, such as stiffness or warmth in the affected joint, followed by intense pain, which may be due in part to rapid joint capsule distention.

Pain is accompanied by objective clinical findings of warmth, a tense effusion, tenderness, limitation of motion, and a joint that is often held in a flexed position. Joint pain responds rapidly to replacement of the deficient clotting factor. If hemostasis is achieved early after onset of hemarthrosis, full joint function may be regained within 12 to 24 hours. If the hemorrhage is more advanced, however, blood is resorbed slowly over 5 to 7 days, and full joint function is regained within 10 to 14 days.

Subacute or Chronic Arthritis

Recurrent hemarthroses, particularly in patients with severe factor deficiency, may lead to a self-perpetuating condition in which joint abnormalities persist in intervals between bleeding episodes. The involved joint is chronically swollen, although painless and only slightly warm. Chronic synovitis, including prominent synovial proliferation with or without effusion, may be present. Mild limitation of motion may be noted, often with a flexion deformity. Factor replacement does not modify these findings.

End-Stage Hemophilic Arthropathy

Long-standing end-stage hemophilic arthropathy has features in common with degenerative joint disease and advanced rheumatoid arthritis. The joint appears enlarged and “knobby,” owing to osteophytic bone overgrowth. Synovial thickening and effusion are not prominent, however. Range of motion is severely restricted, and fibrous

Percentage of joints with:

Any hemarthrosis	Many hemarthroses	Chronic pain	Synovitis	Limitation of motion	Any radiologic abnormality
34.5	13.3	13.9	—	16.9	21.6
54.0	38.5	13.8	9.8	27.0	52.6

Figure 119-1 Distribution of acute hemarthrosis based on a study of 139 patients with hemophilia. Clinical and radiologic features of chronic arthritis in hemophilia. (Adapted from Steven MM, Yogarajah S, Madhok R, et al: Haemophilic arthritis, QJM 58:181, 1986.)

ankylosis is common. Subluxation, joint laxity, and malalignment are frequently present. Hemarthroses decrease in frequency, however.

Septic Arthritis

Until the early 1980s, septic arthritis rarely occurred in hemophilic patients. With widespread occurrence of human immunodeficiency virus (HIV) infection as a result of contaminated factor concentrates, the incidence of this complication has increased significantly.^{11,12} Septic arthritis is seen more often in adult than in pediatric hemophilic patients and is most commonly monoarticular, usually involving the knee. In contrast to spontaneous hemarthrosis, septic arthritis is significantly associated with a temperature greater than 38° C within 12 hours of presentation and articular pain that does not improve with replacement therapy.¹¹ Peripheral leukocyte count may not be elevated, particularly in HIV-positive patients.¹³ A predisposing factor other than hemophilic arthropathy is often identifiable, including previous arthrocentesis or arthroplasty, intravenous drug use, and an infected indwelling venous access catheter. *Staphylococcus aureus* is the most frequently identified organism even in HIV-infected patients, followed by *Streptococcus pneumoniae*.¹³

Muscle and Soft Tissue Hemorrhage

Bleeding into muscles and soft tissue is common in hemophilic patients and may be more insidious than hemarthrosis because of the lack of premonitory symptoms. Bleeding into the iliopsoas and gastrocnemius muscles and the forearm results in well-described syndromes with which the rheumatologist should be familiar. Iliopsoas hemorrhage produces acute groin pain with marked pain on hip extension and a hip flexion contracture. Rotation is preserved, in contrast to intra-articular hemorrhage. If untreated, the expanding soft tissue mass may compress the femoral nerve, causing signs and symptoms of femoral neuropathy.^{6,14} Bleeding into the gastrocnemius muscle can cause an equinus deformity from heel cord contracture.⁶ Finally, hemorrhage into closed compartments can cause acute muscle necrosis and nerve compression.¹⁵ Of particular importance is bleeding into the volar compartment of the forearm, which can cause flexion

deformities of the wrist and fingers. If a compartment syndrome is suspected, compartment pressures should be measured to confirm the diagnosis.

A large intramuscular hemorrhage uncommonly results in the formation of a simple muscle cyst, which clinically appears to be an encapsulated soft tissue area of swelling overlying muscle. Cyst formation in this setting is confined by the muscular fascial plane and most likely results from inadequate resorption of blood and clot. Subperiosteal or intraosseous hemorrhage, in contrast, may lead to a pseudotumor, a rare skeletal complication of hemophilia. Hemophilic pseudotumors are of two types: the adult type, which occurs proximally, usually in the pelvis or femur; and the childhood type, which occurs distal to the elbows or knees and carries a better prognosis.^{16,17}

Conservative early management of muscle cysts and childhood-type pseudotumors is indicated, including immobilization and factor replacement. In adult-type pseudotumors, which usually are refractory to conservative therapy, and in progressive childhood pseudotumors, surgical removal is indicated¹⁶ to prevent serious complications, such as spontaneous rupture, fistula formation, neurologic or vascular entrapment, and fracture of adjacent bone. Aspiration of a pseudotumor or cyst is contraindicated.

DIAGNOSTIC IMAGING

Radiographs

The earliest radiographic changes in hemophilic arthropathy are confined to the soft tissue and reflect acute hemarthrosis. The joint capsule is distended with displacement of fat pads, and an increased hazy density caused by intra-articular blood is noted. Hemarthrosis before epiphyseal plate closure may result in epiphyseal overgrowth and irregularity. Occasionally, premature epiphyseal closure is seen.

With progression of chronic proliferative synovitis, irreversible radiologic changes appear.¹⁸ These changes reflect the inflammatory and degenerative nature of chronic hemophilic arthropathy (Table 119-1 and Figure 119-2A). Certain changes unique to hemophilic arthropathy occur as well (see Table 119-1 and Figure 119-2B). Radiographic findings in hemophilic arthropathy have been recently reviewed.^{18a}

Table 119-1 Radiologic Manifestations of Chronic Hemophilic Arthropathy

Characteristic	Also Seen in
Periarticular soft tissue swelling	RA
Periarticular demineralization	RA
Marginal erosions	RA

A study of serial radiographs of symptomatic joints in hemophilic patients suggests that serial scoring with conventionally accepted techniques may be a cost-effective alternative to magnetic resonance imaging (MRI) in predicting progressive synovial hypertrophy.¹⁹

Other Imaging Methods

MRI is now routinely used to stage hemophilic arthritis accurately to determine optimal treatment and to follow response to therapy.²⁰ A scoring system based on MRI has been proposed.²¹ MRI has been demonstrated to be superior to conventional radiography and computed tomography in the detection of erosions and cysts, bone marrow edema and hemorrhage, and synovial hypertrophy and torn ligaments

(the latter in patients whose radiographs showed widened intercondylar notches).²² As preventive measures improve, it will continue to be important to use the most advanced techniques, including MRI, both to stage hemophilic arthropathy and to assess the benefits of new therapies such as prophylactic infusion.²³ Additionally, MRI and ultrasonography are useful in the detection and quantitation of soft tissue bleeding, cysts, and pseudotumors.^{24,25}

PATHOLOGIC FEATURES AND PATHOGENESIS

Pathologic studies of human hemophilic arthropathy have been limited to synovial specimens obtained at surgery^{26,27} or at postmortem examination and reflect changes of advanced disease only. Studies of experimentally produced hemarthrosis in animals,^{28,29} post-traumatic hemarthrosis in nonhemophilic humans,³⁰ and canine and murine models of hemophilia A³¹⁻³³ have provided an understanding of the earliest changes induced by acute hemarthrosis and their evolution to chronic arthritis.

As reviewed more recently,³⁴ the process most likely includes catabolic activation of synovial cells by exposure to blood components with subsequent cartilage destruction and a direct destructive effect of intra-articular blood on cartilage. A single synovial hemorrhage induces serial changes in the synovial membrane, including early focal villous synovial proliferation and subsynovial diapedesis of erythrocytes, followed by the appearance of perivascular inflammatory cells, patchy subsynovial fibrosis, and intracellular iron accumulation in synovial cells and subsynovial macrophages. With repeated hemarthroses, the synovium becomes grossly hypertrophied and hyperpigmented, with eventual organization into a pannus that invades and erodes marginal cartilage. On histologic examination, villous

Figure 119-2 Radiographic changes of hemophilic arthropathy. **A**, Early arthritis of the knee, showing soft tissue swelling, widening of the femoral condyles and tibial plateau, irregularity of the distal femoral epiphysis, and a few subchondral bone cysts. **B**, More advanced arthritis involving the elbow, showing almost complete loss of joint space and extensive subchondral cyst formation. Widening of the proximal radius is characteristic of hemophilic arthropathy.

Figure 119-3 Proliferative synovitis of hemophilia. Villous hypertrophy of the synovium with pigment deposition in superficial cells. The reaction is mainly synovial cell hyperplasia. Infiltrating inflammatory cells are scarce. (Hematoxylin and eosin, $\times 2500$.)

hypertrophy and subsynovial fibrosis progress, but inflammatory cells are scarce (Figure 119-3).²⁷ Seventy-five percent of synoviocytes contain siderosomes (electron-dense, iron-filled deposits within lysosomes), in contrast to 10% in normal synovium and 25% in rheumatoid synovium.³⁵ Iron deposits are associated with the production of proinflammatory cytokines and synovial inhibition of the formation of human cartilage matrix. Although the inflammatory synovial changes are mild, the synovial production of proinflammatory mediators, including interleukin-1 and interleukin-6 and tumor necrosis factor, approaches that of rheumatoid synovium.³⁴ The articular cartilage is grossly and microscopically abnormal in the setting of recurrent hemarthrosis.²⁸ Areas of cartilaginous fissuring and rarefaction expose sclerotic bone. The remaining cartilage is thin and unevenly distributed, often freely protruding into the joint cavity. Bone erosions appear at weight-bearing surfaces. Loss of matrix glycosaminoglycan occurs and is also seen in degenerative arthritis.^{27,36}

Current studies suggest that recurrent hemarthrosis induces joint destruction in hemophilic arthropathy through direct and indirect effects of iron on the synovium^{35,37} and cartilage,^{36,38} by the degradative effect of proliferative synovium,³⁹ and through an alteration in cartilage biochemical composition similar to that seen in degenerative arthritis. A relationship between hemarthrosis-induced overexpression of oncogenes (e.g., *c-myc* and *mdm-2*) and the dysregulated, tumor-like proliferation of hemophilic synovium has been noted.⁴⁰⁻⁴² Angiogenesis induced by growth factors such as vascular-derived endothelial growth factor may be important in inducing and sustaining a synovial proliferative response to hemarthrosis.⁴²

DIAGNOSIS

In most cases of congenital coagulopathy, the diagnosis has been made before presentation to a rheumatologist. In the

case of hemophilia, if an affected family member is identified, prenatal diagnosis is possible. Because the spontaneous mutation rate in hemophilia is significant, the diagnosis may not be suspected until infancy, when recurrent, large ecchymoses or sustained oral hemorrhages commonly develop in most affected patients. In the case of hemophilia A or hemophilia B, hemarthrosis is usually a later manifestation, but it may be the initial symptom of other, less severe coagulopathies, even in adulthood. When a coagulopathy is suspected, baseline screening tests, including prothrombin time, activated partial thromboplastin time, and platelet count, should be performed. In patients with hemophilia, prothrombin time and platelet count are normal, and activated partial thromboplastin time is prolonged, denoting a defect in the intrinsic clotting cascade. Referral to a hematologist, who obtains the appropriate factor assays, is the next step.

Individuals with factor VIII or IX levels of 1% or less of the normal level have joint and muscle hemorrhages requiring therapy an average four or five times per month. Such patients are classified as having severe hemophilia. Individuals with factor VIII or IX levels greater than 5% of normal are considered to have mild hemophilia and usually bleed only with trauma or at surgery. Occasional “spontaneous” hemarthrosis may occur in such patients, especially in joints damaged by previously undertreated hemorrhage.

Patients whose factor VIII or IX levels fall between these two ranges are considered to have moderately severe hemophilia, and their clinical picture falls somewhere between the extremes. If such patients have had multiple untreated or suboptimally treated hemarthroses with subsequent joint damage, the anatomic instability of these joints will cause frequent and severe bleeding, and the condition will appear clinically more severe than the factor VIII or IX assay might suggest.

TREATMENT OF HEMOPHILIA

Until recent years, factor replacement therapy has been given on demand in most hemophilia centers, that is, factor concentrate has been infused at the earliest sign of a hemorrhage. Because of the introduction of highly purified, safe concentrates, prophylactic treatment is now much more common in countries where this product is available, especially in pediatric patients.^{43,44} Instead of providing infusion when a hemorrhage has occurred, factor concentrate is given regularly three times per week to prevent bleeds. Prophylaxis is started before any joint damage has occurred, usually at approximately 2 years of age, with the goal of minimizing bleeding episodes to no more than four to six per year. Indwelling catheters, such as Port-A-Cath and Hickman lines, are required for factor administration because frequent venipunctures are painful and cumbersome. A recent multicenter prospective randomized controlled trial⁴⁵ confirmed earlier work⁴⁶⁻⁴⁸ and showed that regular prophylactic factor infusion as opposed to episodic factor replacement at the time of hemarthrosis was associated with significantly less joint damage from bleeding episodes with attendant reduction in lifetime disability. Unfortunately, the cost of treatment was enormous, and specifics such as the optimum time to initiate prophylaxis were not addressed. At present, these issues remain

unanswered⁴⁹ and act as “a barrier to widespread acceptance of prophylaxis,”⁴⁵ even in the United States, but especially in the developing world.

With adequate factor replacement, all types of surgery, including joint replacements, can be done. Surgical intervention should be provided for patients with hemophilia, but only at specialized centers with blood bank and coagulation laboratory support and with the participation of a hematologist who specializes in clotting disorders. A surgeon who feels comfortable operating on patients with clotting disorders also is essential. Constant-infusion techniques for administering factor concentrate during and after surgery have made adequate factor levels easier to maintain and have decreased overall perioperative use of factor concentrates.⁵⁰ Many types of commercial factor VIII concentrate are available, most of which are manufactured with recombinant technology.

Factor VIII Replacement

All plasma-derived factor concentrates are virally inactivated by various methods, including exposure to solvent detergent, heat, and pasteurization. Recombinant factor VIII concentrates, manufactured by inserting the human factor VIII gene into a mammalian cell line, are widely available and are used almost exclusively, especially in developed countries.^{51,52} Because human plasma is not used in their production, transfusion-transmitted diseases, such as hepatitis and HIV, are no longer a risk. Recombinant concentrates at doses similar to those of plasma-derived concentrates have been efficacious in the treatment of hemorrhage. Half-life and recovery times for infused factor VIII are similar to those for plasma-derived concentrates. Current prices range from \$0.35 to \$0.90 per unit for factor VIII plasma-derived concentrates and from \$1.00 to \$1.20 per unit for recombinant factor VIII. In most hemophilia centers in the United States, recombinant factor concentrates are the only concentrates used, although high-purity, plasma-derived concentrates are still available. Because these concentrates have made early and intensive home therapy possible, overall costs of health care have greatly declined for patients treated with these materials.

Arginine vasopressin (desmopressin), a vasopressin analogue, can be used in the treatment of mild hemophilia A to increase the endogenous factor VIII level. Desmopressin increases the baseline factor VIII level about threefold, so a baseline level of at least 10% is required for efficacy.⁵³ Because this is not a blood product, it poses no danger of transmitting blood-borne viruses. Although cryoprecipitate contains factor VIII, its use has been discouraged because it is not virally inactivated. It is less safe than concentrates.

Factor IX Replacement

Factor IX is not found in cryoprecipitate or factor VIII concentrate; these two materials are totally ineffective for the treatment of hemophilia B. Fresh-frozen plasma does contain factor IX and has been used in the past. Most fresh-frozen plasma products are not virally inactivated, however, and are less safe than factor IX concentrates.

The principles of treatment are similar to those for factor VIII replacement. Because the half-life of factor IX is longer,

however, it can be given less frequently. Demand therapy is still commonly used; as for factor VIII deficiency, however, prophylaxis is beginning to be used in pediatric patients. Several plasma-derived factor IX concentrates are available, all virally inactivated. In the past, all such concentrates also contained factors II, VII, and X (prothrombin complex concentrates). Currently, only pure factor IX concentrates are used to treat factor IX deficiency. As with factor VIII concentrates, a recombinant factor IX concentrate is available and is widely used. Recovery is less than that of its plasma-derived counterpart, however, and higher doses (approximately 1.5 times calculated levels) must be infused to reach appropriate levels.

Complications of Factor Replacement Therapy

Inhibitor Antibodies

Inhibitor antibodies may develop after exposure to factor concentrate. They occur most often in patients with severe hemophilia after 9 to 30 exposures of replacement therapy, usually before the age of 5 years. A familial predisposition to the development of this complication may be noted. Because bleeding cannot be reliably controlled in patients with inhibitor antibodies, elective surgery in these patients should be done only after careful deliberation.

Inhibitor antibodies in factor VIII-deficient hemophilic patients are immunoglobulin (Ig)G antibodies (usually IgG4) and may have an unpredictable natural history. Low titer and clinically weak antibodies sometimes are easily neutralized by factor VIII and do not undergo anamnestic increases in titer after multiple factor VIII challenges. Such antibodies may rarely become high in titer. In other patients, antibody titers increase after each exposure to factor VIII. Still other patients seem to lose antibody spontaneously despite multiple subsequent factor VIII challenges. The type of antibody response to factor VIII infusion and the patient's clinical response dictate therapy.

Therapy for patients with inhibitor antibodies has been reviewed more recently.⁵⁴ Induction of immune tolerance through frequent administration of factor VIII successfully eliminates inhibitors in 80% of patients. In patients in whom immune tolerance therapy is unsuccessful, several approaches are available for management of acute bleeding episodes, including administration of activated prothrombin complex concentrate or, more recently, recombinant activated factor VIIa (rVIIa, Novo-Seven; Novo Nordisk, Bagsvaerd, Denmark). rVIIa is thought to function directly at the site of injury, causing activation of factor IX and the extrinsic clotting system locally. Porcine factor VIII, which has limited cross-reactivity with the human antibody, was used previously, but has been removed from the market because of contamination with porcine parvovirus. A recombinant form of this protein is being investigated.⁵⁵

Use of immunosuppressives or glucocorticoids has been abandoned in most centers owing to lack of efficacy in this condition and serious side effects. Regimens of regular factor VIII infusions for induction of tolerance have been successful in eliminating the antibody. It has been suggested by some groups that an immune tolerance regimen should be started as early as possible after an inhibitor develops.

Rituximab may be useful for suppressing inhibitor titers in refractory patients.⁵⁶

Inhibitor antibodies against factor IX are exceedingly rare. No efficacious therapy has been generally accepted. Treatment usually includes large and frequent doses of factor IX concentrate. Induction of immune tolerance with elimination of the antibody also has been done, but with less success than with antibodies to factor VIII. Use of large doses of purified factor IX concentrate in some patients with inhibitor antibodies to factor IX has resulted in anaphylactic reactions and nephrotic syndrome secondary to immune complex formation and deposition in the kidney.^{57,58}

Human Immunodeficiency Virus

HIV was introduced into the U.S. blood supply in the 1970s. By the late 1970s, factor concentrate was widely contaminated. By 1982, approximately 50% of patients with hemophilia were infected with HIV.⁵⁹ Currently, approximately 10% to 20% of American hemophilic patients are infected with HIV. As with other infected individuals, CD4⁺ lymphocyte counts and HIV titers are used to guide treatment regimens. Since 1985, in the manufacture of plasma-derived concentrates, a triple barrier to viral contamination of plasma-derived concentrates has been applied: (1) self-exclusion for donors, (2) donor screening with serologic tests for HIV, and (3) viral inactivation during concentrate production. Recombinant concentrates also are now widely available. Acquisition of HIV through factor concentrate in patients with hemophilia has been virtually nonexistent since 1985.

Viral Hepatitis

A second infectious side effect of cryoprecipitate or factor concentrate is hepatitis, which may result from parenterally transmitted hepatitis A, B, C, or G virus; cytomegalovirus; or another as yet unidentified pathogens. In most series, most patients with hemophilia treated before the 1980s have plasma levels of hepatitis B virus surface antibody, and a few (2% to 5%) carry hepatitis B virus surface antigen. Approximately 80% of hemophilic patients transfused before 1990 have antibody to hepatitis C virus,⁶⁰ which, in contrast to hepatitis B virus antibody, is a marker for ongoing infection. Virucidal concentrate treatment methods have reduced, but not eliminated, parenteral transmission of hepatitis B and C viruses. Transmission of hepatitis A and G viruses has been reported with the use of plasma-derived concentrates. Vaccination against hepatitis B and hepatitis A is now recommended for infants born in the United States, and vaccination against hepatitis A is recommended for infants with hemophilia. Transmission of hepatitis has decreased dramatically because almost all pediatric patients are treated with recombinant products.

Therapy for Musculoskeletal Complications of Hemophilia

Acute Hemarthrosis

The most important measure in therapy for acute hemarthrosis is prompt correction of the clotting abnormality by

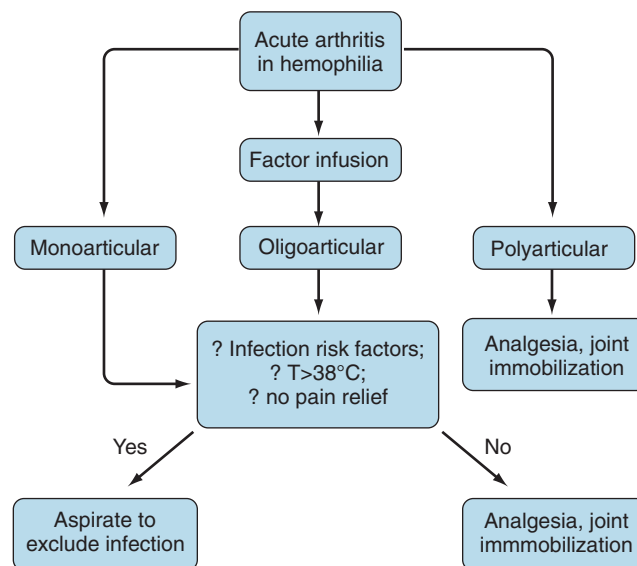

Figure 119-4 Algorithm for acute arthritis in hemophilia.

administration of the deficient factor. Arthrocentesis, if it is accomplished within 24 hours of the onset of symptoms (but after factor replacement), may be symptomatically beneficial in advanced acute hemarthrosis; however, for diagnostic and potentially therapeutic purposes, it should be considered mandatory at any time if suspicion of infection is high.^{12,14} Analgesia and brief joint immobilization for no longer than 2 days often aid in pain control. Subsequently, passive range-of-motion isometric exercise should be initiated to reduce the likelihood of joint contracture (Figure 119-4).

Chronic Hemophilic Arthropathy

Nonsurgical management of hemophilic arthropathy has been reviewed.⁶¹

Conservative. A variety of conservative measures can bring remarkable benefit in the setting of chronic hemophilic arthropathy,⁶²⁻⁶⁵ including the following:

- Prophylactic factor infusions
- Intensive physical therapy for muscle building and increased joint stability
- Periods of avoidance of weight bearing to allow regression of synovitis
- Correction of flexion contractures with wedging casts, night splints, or the judicious use of traction
- Training in sports to allow future maintenance of muscle mass

In modern treatment programs, aspiration of joints with chronic synovial effusions is rarely necessary or of lasting benefit. Failure of these conservative modalities to relieve symptoms or produce regression of synovitis should prompt consideration of other options, including local corticosteroid injections (which have been described as useful),⁶⁶ use of nonsteroidal anti-inflammatory drugs (NSAIDs), synovectomy, and joint replacement in the end stage.

Despite the obvious theoretical contraindications to the use of NSAIDs in hemophilia (i.e., the antiplatelet effects), several NSAIDs may be used safely for short periods as

adjuncts to the conservative regimen. Ibuprofen, salsalate, and magnesium salicylate have been shown in a few patients to be safe and efficacious in reducing joint pain and analgesic dependence,^{67,68} although long-term regression of synovitis and modification of the course of chronic hemophilic arthropathy have not been shown with any NSAID. Selective cyclooxygenase-2 inhibitors of NSAIDs do not have significant antiplatelet effects and theoretically should be safer than conventional NSAIDs in patients with hemophilia. Rofecoxib and valdecoxib have been withdrawn from the market because of a causative link to increased risk of cardiovascular events. Although others are in development, celecoxib, the only remaining cyclooxygenase-2 inhibitor on the market, has not been specifically tested in hemophilic patients and, similar to other NSAIDs, should be used with caution.

Synovectomy. Synovectomy in the setting of hemophilic arthritis has been shown to reduce the incidence of recurrent hemarthrosis and the severity of synovitis. This procedure can be accomplished surgically, arthroscopically, or through intra-articular injection of radioactive colloids or chemical substances. Patients should be considered for synovectomy if, despite aggressive conservative measures as outlined previously, persistent hemarthroses continue with ongoing chronic synovitis. At our center, specific indications for synovectomy include persistence of at least two hemarthroses per month in the same joint accompanied by symptoms and signs of chronic synovitis despite at least 4 months of conservative therapy, including intensive factor replacement. The major drawback to surgical synovectomy remains the observation, confirmed in most series,^{69,70} that joint motion is reduced postoperatively compared with preoperative baseline joint motion, despite intensive rehabilitation.

To overcome this finding and the high cost of hospitalization and factor replacement therapy attendant with surgical synovectomy, arthroscopic synovectomy has been used for chronic hemophilic arthritis in recent years. Most follow-up series report that this technique is as successful as surgical synovectomy and results in less loss of motion,⁷¹⁻⁷³ particularly when continuous passive motion is used in the postoperative period.⁷⁴ The total cost of the procedure is less than that of surgical synovectomy, as is the rehabilitation period. Postoperative bleeding after arthroscopic synovectomy has been associated with poor results.

An alternative to surgical or arthroscopic synovectomy is ablation of the synovium using radioisotopic or chemical agents, as reviewed more recently.^{44,75-77} Such a nonoperative approach has been successful in reducing bleeding episodes by 70% to 80% in patients with hemophilia⁷⁸ and is especially useful in patients with circulating factor inhibitors, in whom surgery is relatively contraindicated. Commonly used radioisotopes in the United States have included colloidal ³²P chromic phosphate, yttrium (⁹⁰Y), and radioactive colloidal gold (¹⁹⁸Au). Rhenium (¹⁸⁶Re) and erbium (¹⁶⁹Er) have also been used with success. Theoretical long-term carcinogenic and teratogenic effects remain major concerns associated with this technique in patients who may have long life expectancies and are still of reproductive age; these effects have limited the use of radioisotopes in the United States, but less so in Europe. Chemical synovectomies using osmic acid, rifampicin, and hyaluronic acid

have been attempted in some European centers with modest success, especially in children.⁷⁵ Short-term results of radioactive and chemical synovectomies are similar, although long-term outcomes may be superior in radioisotopic synovectomy.⁴⁴ Radioactive and chemical synovectomies remain experimental in the United States. Both offer the advantages of being minimally invasive, requiring little factor replacement, and resulting in little morbidity, and both are much less expensive than operative procedures.

Total Joint Replacement. Major orthopedic procedures, including total joint replacement,⁷⁹⁻⁸² have been performed safely and successfully in end-stage hemophilic arthropathy, including in patients with inhibitor antibodies.⁸³ The primary indication for total joint replacement is pain in an involved joint that is refractory to all conservative measures. Careful preoperative planning is imperative, including assessment for the presence of inhibitors, planning for factor replacement, and planning for a multidisciplinary rehabilitative program.⁸⁴ It is a matter of concern, however, that most hemophilic patients in need of total joint replacement are young and may, if they are not infected with HIV, have a long life expectancy. If the procedure is performed at a young age, this virtually ensures the need for one or more revisions during the patient's lifetime. Long-term follow-up studies of total knee replacement in hemophilic patients have shown improved functional scores but conflicting results with regard to prosthetic survival and the incidence of postoperative infection. Although an increased incidence of prosthetic infection and loosening has been noted in hemophilic patients in one large series⁸⁵ (in keeping with many previous smaller reports), a recent 25-year follow-up study encouragingly suggests that the outcome of total knee replacement can approach that of nonhemophilic patients.⁸⁶ This was believed to be due in large part to the use of continuous factor infusions in the perioperative period, in addition to a coordinated multidisciplinary approach by specialists within a hemophilia center. In this setting, total knee replacement has been suggested to be the treatment of choice for advanced hemophilic arthropathy.⁸⁶ Despite this, however, concerns with regard to perioperative complications (paradoxically including deep venous thrombosis),⁸⁷ infection, and late loosening in this population of patients remain. A comprehensive review details the many orthopedic procedures that are now available for alleviating the pain and deformity resulting from hemophilic arthropathy.⁸⁸

CONCLUSION

Gene therapy or repair to cure hemophilia may someday be a reality, although this approach currently is still fraught with serious safety concerns.^{89,90} Until that time, the best therapy for hemophilic arthropathy remains its prevention, and prevention is now achievable in many patients. With improvements in the safety and availability of factor concentrates, prophylactic infusion, although expensive, is now feasible, has been shown to reduce hemarthrosis and improve long-term joint outcomes,⁴⁵ and at some time in the future may be widely available at an affordable cost. In the meantime, through a combination of prevention of hemarthrosis or correction of the hemostatic defect at the earliest

symptom of joint hemorrhage, education of the patient, application of comprehensive care, and emphasis on the importance of physical activity to maintain muscle mass, the incidence of new or progressive arthropathy can be significantly reduced.⁹¹

KEY POINTS

The hemoglobinopathies differ in their pattern and severity of musculoskeletal manifestations.

Sickle cell disease is characterized by painful vaso-occlusive crises, which stem in part from bone and muscle ischemia.

Patients with sickle cell disease (rarely sickle trait) suffer frequent bone infarctions in the long bone shafts, especially in the humeral and femoral heads.

Sickle cell synovial infarctions may mimic acute septic or gouty arthritis.

Salmonella osteomyelitis is a rare complication of sickle cell disease; septic arthritis is usually due to *Staphylococcus* (a significant minority of patients have gram-negative infections).

The thalassemias rarely cause arthritis; however, the iron chelator deferiprone has been associated with severe joint pain.

CLINICAL BIOLOGY OF THE HEMOGLOBINOPATHIES

The hemoglobinopathies comprise a group of genetic disorders characterized by the presence of variant hemoglobins in circulating erythrocytes. Clinical manifestations differ dramatically based on the physicochemical behavior of the abnormal hemoglobin, and how the variant protein chains interact with other hemoglobin chains, the erythrocyte membrane, ion transporters, and oxygen. Some variant hemoglobins exhibit abnormal oxygen-dissociation curves or erythrocyte fragility resulting in dyspnea, fatigue, or hemolysis. Relevant to rheumatologic manifestations, the red cells of patients with sickle cell variants are structurally rigid, and as they traverse the microvasculature are unable to deform in small vessels; they occlude the vascular lumina and abnormally adhere to endothelial cells. As a result, patients with homozygous hemoglobin S disorder (sickle cell anemia, Hgb SS) exhibit a broad range of clinical syndromes caused by variable intensity of the intracellular sickling process and resultant vaso-occlusion. The degree of hemoglobin sickling dictates the complications and is affected by several factors, including the presence and amount of alternative hemoglobin forms (e.g., fetal hemoglobin, Hgb F). Our molecular understanding of this process has grown over the past 30 years,¹ and greater understanding has contributed to the development of management strategies for treating and limiting these vaso-occlusive episodes.

Rheumatologic Manifestations of Hemoglobinopathies

BRIAN MANDELL

Sickling and vaso-occlusion occur more in tissues with low oxygen tension and lower pH. Ischemic phenomena, sometimes with lasting sequelae, seem to be particularly common in kidney, eye, bone, synovium, muscle, and skin. Other striking organ involvement may include stroke, mitral valve damage, splenic infarction with hypofunction, and acute pulmonary syndromes. Under certain conditions, these complications may mimic systemic inflammatory, autoimmune, or primary thrombotic disorders.

As a result of chronic hemolysis, some of the hemoglobinopathies such as the thalassemias (imbalanced synthesis of normal globin chains) result in hyperplastic marrow with skeletal abnormalities.² Patients may require frequent transfusions, which can lead to syndromes associated with iron overload, or painful joint complications from the required use of iron chelators.

CLINICAL FEATURES OF MUSCULOSKELETAL SYNDROMES LINKED TO HEMOGLOBINOPATHIES

The recurrent painful crisis is the hallmark of sickle disease, with marked pain in the muscles and joints, as well as in the abdomen and chest. These episodes involve muscles and joints and are sometimes difficult to localize; frequently, the pattern of pain is repeated in recurrent crises. Pain that is clearly localized to an isolated area, such as a single shoulder, right upper quadrant, buttock, or groin, warrants aggressive and rapid evaluation. The pain may be severe enough to require narcotics, but extreme diligence must be paid to the development of individualized pain control care plans to limit the expectation and delivery of escalating narcotics in all patients. Painful crises may begin as early as 6 months of age as the concentration of fetal hemoglobin F wanes, permitting sickling to occur more readily.

Avascular necrosis (AVN; osteonecrosis) and ischemic bone syndromes are common in both adults and children with sickle cell anemia (but are not usually seen in patients with heterozygous Hgb S disease—sickle trait³). In very young children, repeated vaso-occlusive crises involving growing small bones of the hands and feet cause the *hand-foot syndrome*, characterized by diffuse painful hand/foot swelling, which may be accompanied by low-grade fever. Radiographic changes may be seen approximately 10 days after the onset of symptoms; these consist of subperiosteal new bone formation in the hands and feet. Cortical thinning, multiple irregular intramedullary deposits, and areas of spotty destruction and formation of periosteal new bone may appear later. These changes can lead to a “moth-eaten” appearance.⁴ AVN is often multifocal but characteristically

affects the femoral heads.⁵ The pain may be of acute onset or may progress insidiously from intermittent pain to pain with use, and finally to constant discomfort or severe pain at rest. Frequently, this condition is diagnosed in young to middle-aged patients who have experienced years of vaso-occlusive crises. Presumably, it occurs as the result of multiple ischemic and occlusive episodes, resulting in bone death as well as progressively increased intraosseous pressure. The prevalence of femoral head AVN is likely greater than 40%. Humeral heads are frequently affected. AVN can mimic a true arthritis with the presence of significant synovial effusion. The pathogenesis of these noninflammatory effusions is not certain, but they may result from hydrostatic pressure increases in vessels draining into the necrotic bone.

Noninfectious arthritis is well described in the setting of acute vaso-occlusive crisis.⁶⁻⁸ Most patients have homozygous SS disease, but a few may have hemoglobin SC (Hgb SC) disease or hemoglobin S-beta thalassemia (β -thalassemia). Crystal-induced arthritis and infection should be excluded by synovial fluid analysis and culture as appropriate. Some of the effusions (monoarticular or oligoarticular) accompany painful crises and joint examination may reveal that adjacent bone is more tender than the joint capsule itself. Almost all synovial fluids are noninflammatory, hence the possibility that bone infarction with a “sympathetic” or transudative effusion offers a pathologic explanation for these effusions. Polyarthritis with minimal or mildly inflammatory fluid has been described in the setting of crisis.⁷ In a series of 70 patients with sickle disease (including Hgb SC disease and Hgb S-thalassemia) followed prospectively, 32 had joint manifestations (30 with Hgb SS disease),⁶ indicating that if carefully looked for, articular involvement is fairly common. Most cases of acute monoarticular and oligoarticular arthritis happened in the setting of a painful crisis, but a very significant subgroup (44%) exhibited arthritis and fever as major symptoms (infection was excluded). In this series, synovial fluid analyses were striking. Sickle cells were seen in many of the synovial fluid samples—an observation that has been noted by others. Whereas cultures were negative and no crystals were observed, many of the synovial fluid samples were inflammatory in cellular appearance with neutrophilic predominance. Nonetheless, arthritis lasted only a mean of 5 days.⁶ An ankle arthritis associated with new or worsening distal leg ulcers has also been described⁸; both may result from occlusive small vessel disease. The synovial histopathology in sickle cell–associated arthritis is generally fairly bland—minimal inflammation with some intimal proliferation and vascular congestion with occasional thrombosis has been reported.⁹

Joint and bone infections are well-recognized complications in patients with sickle cell disease, although they are not particularly common. *Salmonella* is an unusual cause of musculoskeletal infection associated with sickle disease.¹⁰ It is more frequent in children than in adults, and more frequently will result in osteomyelitis rather than septic arthritis. Reasons for susceptibility to this specific organism remain unclear. Patients with sickle cell anemia exhibit potentially altered gut mucosal integrity due to small vessel ischemic injury, splenic infarction with dysfunction, and decreased complement activation, all of which may render patients at increased relative risk. Moreover, damage to

joints from repetitive ischemic injury provides a nidus for bacterial “seeding.” The diaphysis is most commonly involved in osteomyelitis, although infection may involve the epiphysis, and bacteria may thereby migrate to the joint space.

In a recent retrospective study of 2000 consecutive adults with sickle cell disease, 59 (3%) were found to have had septic arthritis.¹¹ The hip was involved in 61% of recorded cases—a disturbing observation in that this is a joint that physicians are often reluctant to aspirate and for which it is often tempting on clinical grounds to attribute acute pain to hip AVN. Also of note, in this study from France, no cases of *Salmonella* were reported. Most infections were due to *Staphylococcus aureus*, as observed in other series of patients with septic arthritis without sickle disease. A relatively large proportion of gram-negative infections theoretically could be due to increased bacterial translocation across the bowel mucosa. The authors documented a strong association in these adults with the presence of previous childhood osteomyelitis or AVN. Overall, *Salmonella* infection seems to be more strongly associated with osteomyelitis in patients with sickle cell disease¹⁰ than in those with arthritis. It is important to note that osteomyelitis may be multifocal.

Sickle cell disease is associated with hyperuricemia, likely due to increased uric acid generation associated with hemolysis and erythroid proliferation. Gout has been described in young patients with sickle disease. Although an infrequent occurrence in young patients, it is generally unexpected and can be confused with other more common causes of acute joint pain in these patients.¹²

Patients with thalassemias have rarely been described as having arthritis or joint pain associated with their dysregulated hemoglobin synthesis. However, chelation therapy with deferiprone, which is often needed to reverse the iron load from frequent transfusions, has been associated with multiple musculoskeletal complications.¹³ Arthralgias seem to be particularly common, perhaps in 20% of patients, although arthritis has been described. Whether some of these patients may have been experiencing a reaction to periarticular and synovial iron overload, and not directly to the drug, is difficult to ascertain given short-term follow-up after drug withdrawal. Successful response to nonsteroidal anti-inflammatory therapy has been suggested by several authors to indicate a useful palliative therapy.¹⁴

DIFFERENTIAL DIAGNOSIS AND DIAGNOSTIC TESTS

The approach to patients with hemoglobinopathies who experience acute monoarticular or oligoarticular arthritis should be no different than that taken with other patients. However, as noted previously, concern about and therefore vigilance concerning infection, AVN, and “true” sickle cell arthritis should be greater. Thus, arthrocentesis should be performed early in the diagnostic process. Patients with sickle cell disease and ongoing hemolysis often have a leukocytosis, and older literature suggests that some patients may exhibit a blunted erythrocyte sedimentation rate (ESR) response to inflammatory stimuli; however, C-reactive protein (CRP) should be reasonably reliable. Note that not all patients with septic arthritis have markedly elevated

acute phase reactants; hence no reliable substitute for arthrocentesis has been found with fluid culture performed to diagnose or exclude an infected joint. Indirect serologic studies, such as rheumatoid factor, anticyclic citrullinated protein antibodies, and antinuclear antibodies, generally should be avoided in the initial workup of acute monoarticular and oligoarticular arthritis; this is no different in the patient with a hemoglobinopathy. No imaging test will reliably distinguish infection from crystalline arthritis or sickle cell arthritis (synovial infarction).

In patients experiencing diffuse crisis pain, careful examination must be performed to find specifically affected joints. Infection can trigger a generalized crisis. It should be remembered that joint pain not worsened by provocative physical examination may be due to referred pain, and such causes as splenic infarction (left shoulder), necrotic gallbladder or pulmonary infarction with effusion (right shoulder), and periarticular osteomyelitis or bone infarction should be considered in the differential diagnosis.

AVN is diagnosed as in other patients with suspected necrosis. Synovial fluid, if present, is bland. Radiographs are insensitive (flattening and the “crescent sign” are not early findings). Magnetic resonance imaging (MRI) is much more sensitive in demonstrating the necrotic process and marrow edema.

TREATMENT

Treatment is generally supportive and analgesic based, once infection and gout have been excluded. Advances have been made in limiting the number of vaso-occlusive crises, but in general, most patients continue to experience painful attacks.¹ For most patients with transient arthritis associated with crises, treatment usually involves analgesics and hydration. Intra-articular corticosteroids are not useful, and as noted, the risk of AVN is already heightened. If infection is suspected by detection of inflammatory synovial fluid, empiric antibiotics should be instituted until culture results have been returned; it should not be assumed that the inflammatory fluid is due to sickle arthritis until cultures are found to be negative. It is far more critical to adequately cover for staph species (including methicillin-resistant *Staphylococcus aureus* [MRSA]) than to cover for salmonella alone, although a recent study¹¹ suggests the need for broad gram-negative coverage as well. In the setting of osteomyelitis, every effort should be made to obtain culture definition of the infecting organism before a prolonged course of antibiotic therapy is initiated.

No “proven” treatment approaches for AVN are known (see Chapter 103); conservative methods, such as avoidance of weight bearing with crutches and bed rest, have been used widely, but without proven success.¹⁵ Core decompression is a procedure that is commonly used to treat

AVN at early stages; however, its use is based mainly on orthopedic case series, and formal trial-based evidence for this approach is lacking. Moreover, use of non-weight-bearing crutches may be problematic because AVN of the humeral heads may also be present, making the use of crutches difficult. Nonetheless, given the young age of patients with AVN, delaying the initial total hip arthroplasty is believed by many to be rational; core decompression may relieve some of the pain, at least temporarily. Authors have expressed concern that the failure rate for total hip arthroplasty is especially high among patients with sickle disease—another reason why some surgeons prefer to delay this procedure in younger patients with sickle disease. Ultimately, explanation, patient education, and early involvement of the multidisciplinary team will offer additional support for this patient group, given the paucity of clinical evidence supporting therapeutic decisions.

Endocrine Diseases and the Musculoskeletal System

MAURIZIO CUTOLO

KEY POINTS

Both hypothyroidism and hyperthyroidism are characterized by frequent symptomatic involvement of the musculoskeletal system.

Diseases of the parathyroid gland can manifest in bone and muscle presentations. The most important joint manifestation of primary hyperparathyroidism is calcium pyrophosphate deposition (CPPD) disease.

Cushing's disease, a subtype (80%) of Cushing's syndrome, is caused by a pituitary adenoma, which is a benign tumor resulting in excess adrenocorticotrophic hormone (ACTH), whereas iatrogenic Cushing's syndrome is secondary to exogenous high-dosage long-term glucocorticoid therapy. Varied musculoskeletal manifestations may arise, which may be indolent and require high levels of clinical vigilance for detection.

Diabetes mellitus can manifest a variety of musculoskeletal presentations in joints, in long bones, and in connective tissues. Several manifestations are characterized by tissue fibrosis. Abnormal tendon biology may contribute to these presentations. Charcot's diabetic osteoarthropathy is a severe, destructive form of degenerative arthritis resulting from underlying diabetic neuropathy.

Musculoskeletal manifestations are a common presenting feature of endocrine disease; therefore, a high level of vigilance should be maintained during initial and ongoing assessment of patients with bone, muscle, and soft tissue complaints. Similarly, endocrine disease can arise in the treatment of rheumatic diseases, especially with the use of glucocorticoids. Whereas the underlying mechanisms of many such presentations remain uncertain, their association is sufficiently common as to merit detailed consideration in the history and examination of all new rheumatic disease presentations, and superficial endocrine assessment should form a part of the routine early investigation of new-onset arthralgia and myalgia patients. This chapter addresses some of the more common musculoskeletal elements of endocrine syndromes.

HYPOTHYROIDISM

Deficiency of thyroid hormone leads to the state of hypothyroidism. The most common cause is Hashimoto's thyroiditis, an autoimmune process in which lymphocytic infiltration and fibrous tissue accumulation cause replacement of normal thyroid tissue and thereby gland dysfunction.¹ The incidence of autoimmune hypothyroidism (Hashimoto's thyroiditis) is increased in patients with systemic sclerosis, as well as with systemic lupus erythematosus

(SLE), rheumatoid arthritis (RA), mixed connective tissue disease, Sjögren's syndrome, and polymyositis.² Most patients develop antibodies against thyroid peroxidase and/or thyroglobulin.³ Hashimoto's thyroiditis is associated with HLA-B8, HLA-DR3, HLA-Aw30, and HLA-DR5.⁴ Some patients with Hashimoto's thyroiditis also exhibit antinuclear antibodies, and many have anti-DNA antibodies; despite this, overt SLE is uncommon. Other potential causes of thyroid gland dysfunction include treatment with radioactive iodine (¹³¹I) for Graves' disease and drug-induced hypothyroidism, for example, associated with amiodarone, iodine (i.e., Wolff-Chaikoff effect), or other drugs.⁵⁻⁸ In addition, hereditary disorders of the iodothyronine synthesis pathway (thyroxine [T₄] and triiodothyronine [T₃]), as well as pituitary tumors and related surgical resections, are possible causes.^{9,10}

Hypothyroidism can cause a broad range of symptoms associated with mild (e.g., fatigue, weight gain, cold intolerance, mental slowing, muscle cramping, bradycardia) to severe complications (e.g., heart enlargement, myxedema coma [rare]). Neuromuscular and musculoskeletal manifestations are observed in many patients. These manifestations can occur at any time in the disease process and include weakness, joint and muscle pain, aching, and stiffness.¹¹ Overall, 30% to 80% of hypothyroid patients manifest neuromuscular symptoms, depending on the severity of hypothyroidism, whereas weakness is observed in almost 30% of patients.¹² More rarely, hypothyroid myopathy manifests as a polymyositis-like illness with proximal muscle weakness and an increased creatinine phosphokinase level. It may also present as muscle enlargement (pseudohypertrophy); in adults, this condition is called *Hoffmann's syndrome*.¹³ In children with hypothyroid disease (cretinism), a pattern of proximal weakness and diffuse muscle enlargement is known as *Kocher-Debre-Semelaigne syndrome*.¹⁴ Several case reports describe rhabdomyolysis associated with hypothyroidism; in these cases, hypothyroidism is thought to have been causative.¹⁵ Myxedema represents a phenomenon in which thickening of muscle tissue occurs after light percussion in approximately 30% of patients; however, it is not entirely specific for the latter.¹⁶ Myxedema is likely caused by delayed calcium reuptake by the sarcoplasmic reticulum, which thereby prolongs muscle contraction. This prolongation of muscle contraction is thought to be related to the development of muscle hypertrophy. A further neuromuscular manifestation concerns peripheral neuropathy. In particular, carpal tunnel syndrome is found in 15% to 30% of patients with hypothyroidism.¹⁷

HYPERTHYROIDISM

Hyperthyroidism (Graves' disease) may affect the musculoskeletal system in several ways; the most common manifestation is osteopenia and potentially osteoporosis. The latter may occur in patients with idiopathic Graves' disease but also in those with iatrogenic hyperthyroidism.¹⁸ Failure to recognize the declining need for thyroid replacement with age is a further important cause of iatrogenic hyperthyroidism in older women. For this reason, patients with hypothyroidism who are on thyroid hormone and estrogen therapy should have thyroid-stimulating hormone levels monitored and the dose readjusted to keep the thyroid-stimulating hormone level within the normal range.¹⁹ Bone density has been shown to increase after correction of the hyperthyroid state.²⁰

Pretilial myxedema is a syndrome of painless nodules that occur over the pretibial areas; virtually all affected patients have concomitant Graves' ophthalmopathy.²¹ Cutaneous lesions vary in size, ranging from nodules with a diameter of 1 cm to very large lesions covering most of the pretibial surface.²² The lesions are colored differently—from pink to a light purple hue—and can be misdiagnosed as erythema nodosum. In contrast to erythema nodosum, however, the lesions are painless. They are caused by the accumulation of hyaluronic acid in the skin and in some cases exhibit a shiny appearance resembling systemic sclerosis or morphea.²³

Hyperthyroidism may be associated with changes in the nails, including onycholysis, or elevation of the nail from the nail bed, and clubbing.²⁴ Clubbing usually is part of the condition known as *thyroid acropachy*, a rare manifestation of hyperthyroidism associated with periostitis around the metacarpal joints and distal soft tissue swelling of the digits.²⁵ This condition is not clearly related to levels of thyroid hormone, and it may be seen after the patient has reverted to the euthyroid state.

Proximal muscle weakness, a common complication of hyperthyroidism, is present in most patients. Most patients have lost weight and have other evidence of loss of muscle mass.²⁶ Proximal muscle weakness reverts rapidly with correction of the hyperthyroid state, suggesting a direct metabolic link to thyroxine effector function. Perhaps related to the proximal myopathy, adhesive capsulitis of the shoulder seems to be increased in patients with hyperthyroidism.²⁷ In these patients, the condition can be insidious and difficult to treat, with frozen-shoulder syndrome often the initial manifestation.

Strong relationships have been noted between Graves' disease and Hashimoto's thyroiditis and other rheumatic diseases. Seventy-five percent to 90% of patients with Graves' disease have antinuclear antibodies, and a proportion also express anti-DNA antibodies, despite the fact that overt SLE is uncommon.³ Graves' disease is associated with HLA-B8, HLA-A1, HLA-Cw7, and HLA-DR3, and combinations of these antigens correlate with persistent disease.²⁸

HYPOPARATHYROIDISM

Hypoparathyroidism is usually secondary to surgical removal of the parathyroid glands and commonly is characterized by

proximal muscle weakness related to the degree of hypocalcemia.²⁹ This condition responds rapidly to treatment with vitamin D and calcium. Other common musculoskeletal manifestations of hypoparathyroidism include osteomalacia and rickets, which are discussed elsewhere. Idiopathic hypoparathyroidism is a rare disorder, seen as part of DiGeorge's syndrome with thymic hypoplasia.³⁰ Pseudohypoparathyroidism, known as *Albright's hereditary osteodystrophy*, is caused by end-organ resistance to the effects of parathyroid hormone.³¹ Pseudohypoparathyroidism is due to a defect in GNAS1 (guanine nucleotide binding protein, alpha-stimulating activity polypeptide 1).³² Patients show persistent hypocalcemia and hyperphosphatemia, but parathyroid hormone levels are consistently elevated. Type Ia pseudohypoparathyroidism, which is autosomal dominant, is characterized by short stature, calcification of perispinal ligaments, and, usually, mental retardation.³³ Patients may present with shortening of the fourth metacarpal and metatarsal bones, and instead of the usual knuckle appearance over the fourth metacarpal head, these individuals have a dimple. Patients affected by type Ib pseudohypoparathyroidism also show resistance to parathyroid hormone but have normal phenotype.³⁴ Type Ia pseudohypoparathyroidism is almost always inherited maternally, and type Ib is inherited paternally.

HYPERPARATHYROIDISM

Primary hyperparathyroidism results from hyperfunction of the parathyroid glands themselves. The condition is characterized by hypersecretion of parathyroid hormone (PTH) caused by adenoma, hyperplasia, or, rarely, carcinoma of the parathyroid glands.³⁵ Secondary hyperparathyroidism comprises the reaction of the parathyroid glands to hypocalcemia caused by pathologic conditions other than parathyroid pathology (e.g., chronic kidney disease).³⁶ The most important joint manifestation of primary hyperparathyroidism is calcium pyrophosphate deposition (CPPD) disease, a disorder with varied clinical manifestations attributed to precipitation of calcium pyrophosphate dihydrate crystals in the connective tissues.^{37,38} *Chondrocalcinosis* refers to radiographic evidence of calcification in hyaline and/or fibrocartilage.³⁹ *Pseudogout* refers to clinically evident acute synovitis that results from shedding of crystals in the joint space after rupture of a CPPD deposit; it is characterized by red, tender, and swollen joints that may resemble gouty arthritis⁴⁰ (see Chapter 96). CPPD crystal deposition disease is a polyarticular arthritis (i.e., it leads to inflammation of several joints), although it can initially present as monoarthritis.⁴¹ Diffuse idiopathic skeletal hyperostosis (DISH) and pseudoankylosing spondylitis are considered additional possible forms of calcium pyrophosphate dehydrate crystal deposition disease (CPPD CDD).⁴² These syndromes are considered in detail in Chapter 96.

Some patients with long-standing hyperparathyroidism report proximal muscle weakness—a condition rapidly reversed by removal of the parathyroid adenoma.⁴³ In these patients, the muscle enzymes are normal, and electromyography and muscle biopsy reveal a picture most consistent with denervation. In secondary hyperparathyroidism associated with advanced renal disease, numerous bone and articular abnormalities are described.⁴⁴ The musculoskeletal

changes of renal osteodystrophy resulting from secondary hyperparathyroidism include erosive arthritis in the hands, resorption of the distal clavicle, and erosions in the axial skeleton.⁴⁵ In children, widespread bone deformities of osteitis fibrosa cystica can be very disabling.⁴⁶ Other musculoskeletal manifestations of advanced renal failure include aluminum-induced osteomalacia³³ and β 2-microglobulin amyloidosis.^{47,48}

ADRENAL GLAND DISORDERS

Primary Cushing's disease is caused by a pituitary adenoma, which is a benign tumor resulting in excess adrenocorticotrophic hormone (ACTH).^{49,50} It may also arise from adrenal adenomas. Iatrogenic Cushing's syndrome (hypercortisolism/hyperadrenalism) secondary to exogenous high-dose long-term glucocorticoid therapy is the most common condition involving adrenal hormones that mediates adverse effects on the musculoskeletal system.⁵¹ Osteonecrosis, a common late complication of high-dose glucocorticoid therapy, may first become evident months or years after glucocorticoid therapy has been discontinued.⁵² It is observed less commonly after short courses of therapy, however, or after intermittent high-dose intravenous therapy, although clinical vigilance is required. Because rheumatic patients receiving high-dosage glucocorticoid therapy have associated diseases characterized by joint pain, the risk of osteonecrosis should be considered, particularly in the differential diagnosis. Use of the lowest acceptable dose of glucocorticoids has reduced the risk of osteonecrosis.^{53,54}

Steroid-induced myopathy may be difficult to recognize in patients being treated for primary or secondary inflammatory rheumatic conditions, particularly myopathies.⁵⁵ However, steroid myopathy is characteristically more severe in the pelvic girdle. It may come on gradually or abruptly, starting with weakness and muscle aching, and can be sufficiently severe to render patients bedbound.⁵⁶ Biopsy specimens or T2 relaxation times are compatible with muscle fiber atrophy, whereas muscle enzymes are normal.⁵⁷ Long-acting and fluorinated glucocorticoids are more likely to induce myopathy, and treatment usually requires ultimate discontinuation of glucocorticoids before any improvement is seen; weeks or months may pass before muscle strength begins to return.⁵⁸

Osteopenia as a secondary effect of hypercortisolism (primary or secondary) is independent of degree or duration of hypercortisolism (adenoma) but may be related to the total dose and duration of glucocorticoid therapy and is more frequent with dosages greater than the equivalent of 7.5 mg/day of prednisone.^{59,60} Prophylaxis is recommended, and regimens shown to be effective in preventing or treating glucocorticoid-induced osteoporosis must include calcium, vitamin D₃, and bisphosphonates.⁶¹

Cushing's disease may be confused with primary musculoskeletal disease, including polymyalgia rheumatica, polymyositis, or statin myopathy, or it may be mistaken for back pain that may arise from osteoporotic fractures or other pathologies.⁶² In Cushing's syndrome secondary to ectopic adrenocorticotrophic hormone production, glucocorticoid serum levels may be extremely high, inducing severe myopathy and additional complications such as steroid

psychosis.⁶³ Several other side effects of glucocorticoids on the musculoskeletal system are less well understood. Some patients describe intense joint pain, frequently most severe in the knees, when high doses of glucocorticoids are started. This pain typically resolves even if the dose is left unchanged.

Adrenal insufficiency is classified into three subtypes based on where the abnormality is based in the hypothalamic-pituitary-adrenal (HPA) axis.⁶² Primary insufficiency is caused by adrenal gland damage (Addison's disease). The secondary form is related to insufficient corticotropin (ACTH) from the pituitary gland. The tertiary form is related to insufficient corticotropin-releasing hormone (CRH) generated from the hypothalamus. Acute adrenal insufficiency, or adrenal crisis, is severe and is characterized by shock. Primary adrenal insufficiency (Addison's disease) is almost exclusively autoimmune (now only rarely related to tuberculosis) and is characterized by weakness, weight loss, abdominal pain, hyperpigmentation, nausea, and hypotension.⁶⁴ Secondary adrenal insufficiency can be related to destruction of the pituitary gland or to deficiency of ACTH. Classically, it is associated with hemorrhage of the pituitary gland, or thrombosis, or it may be noted during infiltrative processes such as those seen when sarcoidosis affects the pituitary gland. Glucocorticoid use and subsequent withdrawal can cause secondary or tertiary adrenal insufficiency. Iatrogenic Addison's disease can be subtle because mineralocorticoids are still being produced; salt wasting, hyperkalemia, and postural hypotension are usually less impressive; and hyperpigmentation is not seen because the pituitary is suppressed. Adrenal insufficiency, particularly in such circumstances, can mimic fibromyalgia syndrome.⁶⁵ Tertiary adrenal insufficiency is most commonly related to withdrawal of glucocorticoids.⁶⁶ Glucocorticoid-induced adrenal insufficiency can be caused by several mechanisms, including decreased hypothalamic synthesis of CRH, blockade of the actions of CRH on the anterior pituitary, and, after prolonged or profound deficiency of ACTH, adrenal atrophy. As in idiopathic Addison's disease, features may not be evident unless the individual undergoes a new exogenous stressful condition, such as surgery or infection. Adrenal insufficiency (adrenal crisis) is a rare disorder that usually manifests with gradually evolving clinical symptoms and signs.⁶⁷ Occasionally, acute adrenal insufficiency (crisis) can become a life-threatening condition as the result of acute interruption of a normal or hyperfunctioning adrenal or pituitary gland, or sudden interruption of adrenal replacement therapy. Addisonian crisis has been seen even in individuals still receiving physiologic or "replacement" doses of glucocorticoids. It should be assumed that individuals taking glucocorticoids at greater than the equivalent of 5 mg/day of prednisone have a pituitary-adrenal axis unable to respond to severe stress (medical and surgical stress, concomitant use of certain medications); consequently, increases in the glucocorticoid dose should be considered in the acute setting.

Musculoskeletal Manifestations and Steroid Deficiency

The so-called steroid withdrawal syndrome consists of widespread arthralgias, myalgias, malaise, and sometimes

low-grade fever.⁶⁸ It may be seen when high-dose glucocorticoids have been used for nonrheumatic conditions, such as asthma or inflammatory bowel disease, and it arises from suppression of the pituitary-adrenal axis. Moreover, abrupt reduction of the dose of glucocorticoid can cause a severe rebound flare of the underlying disease, at least in rheumatic diseases.⁶⁹ This condition may arise even though the dose of glucocorticoid remains in the pharmacologic range. It is important to recall that treatment with glucocorticoids should not be stopped until endogenous synthesis of glucocorticoids is fully efficient. Administration of low-dose “modified-release” glucocorticoids, which addresses appropriate timing of administration (at night, reflecting HPA circadian rhythms), has been shown to reduce the severity of this syndrome.⁷⁰⁻⁷²

Subclinical hypoadrenalism associated with insufficient production of cortisol may arise in conditions of chronic stress (e.g., interpersonal conflict, chronic inflammatory disease state), especially in the elderly.^{73,74} In this circumstance, a new stressor may induce the development of polymyalgia rheumatica^{75,76} (see Chapter 88).

DIABETES MELLITUS

Diabetes mellitus (DM) may affect the musculoskeletal system in myriad ways. Many rheumatologic disorders have been observed more frequently among individuals with DM than in the general population.⁷⁷ The metabolic perturbation characterized by diabetes (including glycosylation of proteins; microvascular abnormalities with damage to blood vessels and nerves; and accumulation of extracellular matrix proteins in skin and periarticular structures) results in overall changes in the connective tissue.⁷⁸ Musculoskeletal complications are most commonly seen in patients with a long-standing history of type 1 diabetes, but they also may be observed in patients with type 2 diabetes.⁷⁹ Some of these complications have a direct association with diabetes, whereas others have a suggested but unproven association (Table 121-1).

Table 121-1 Rheumatic Complications of Diabetes Mellitus (DM)

Conditions Limited to DM
Diabetic muscle infarction
Conditions Occurring More Frequently in DM
Diabetic cheiroarthropathy, or limited joint mobility, or stiff hand syndrome
Flexor tenosynovitis, or trigger finger
Dupuytren's contracture
Carpal tunnel syndrome
Adhesive shoulder capsulitis, or frozen shoulder
Calcific shoulder periarthritis (tendinitis)
Reflex sympathetic dystrophy, or shoulder-hand syndrome, or complex regional pain syndrome
Diabetic osteoarthropathy, or Charcot's arthropathy, or neuropathic arthropathy
Conditions Sharing Risk Factors of DM
Diffuse idiopathic skeletal hyperostosis
Gout/Pseudogout
Osteoarthritis

Hands

Diabetic cheiroarthropathy, also known as *diabetic stiff hand syndrome* or *limited joint mobility syndrome*, has been reported in 8% to 50% of all patients with type 1 diabetes and is also seen in type 2 diabetic patients.⁸⁰ Prevalence increases with the duration of diabetes, and the disorder is associated with and is predictive of other diabetic complications. Diabetic cheiroarthropathy is characterized by thick, tight, waxy skin reminiscent of systemic sclerosis with limited joint range of motion (inability to fully flex or extend the fingers) and possible sclerosis of tendon sheaths. Once again, the underlying causes are thought to be multifactorial and include increased glycosylation of collagen in the skin and periarticular tissue, decreased collagen degradation, and diabetic microangiopathy.⁸¹ As a consequence, flexion contractures of the fingers may develop at advanced stages, and the classic indication of the presence of this condition is known as the “prayer sign,”⁸⁰ which is seen as a patient's inability to press the palms together completely without a gap remaining between opposed palms and fingers.

Another frequent complication affecting the hands is *flexor tenosynovitis* (or trigger finger); patients describe a catching sensation or a locking phenomenon that may be associated with pain in the affected fingers.⁸² Physical examination reveals a palpable nodule, usually in the area overlying the metacarpophalangeal joint, and thickening along the affected flexor tendon sheath on the palmar aspects of the finger and hand. Flexor tenosynovitis is thought to have the same pathogenesis as diabetic cheiroarthropathy; its prevalence is similarly related to the duration of diabetes.⁸² Abnormalities of matrix metalloproteinases and their tissue inhibitors have been demonstrated in diabetic fibroblast culture systems *ex vivo* (Brown I and McInnes IB, personal communication). *Dupuytren's contracture* results from thickening, shortening, and fibrosis of the palmar fascia; nodule formation along the fascia is often detected.⁸³ Flexion contractures of the fingers may result, usually at the fourth finger but sometimes involving any of the second through fifth digits. Dupuytren's contracture has been reported in 16% to 42% of diabetic patients, with pathogenesis that is thought to be the same as that for cheiroarthropathy. Once again, the prevalence of this condition increases with disease duration, but Dupuytren's contracture also may be seen early in the course of the disease.

Another frequent complication of DM is *carpal tunnel syndrome* (CTS), which is observed in up to 20% of diabetic patients; the specific relationship to diabetes is thought to be median nerve entrapment caused by diabetes-induced connective tissue alterations, as previously mentioned.⁸⁴ CTS usually is diagnosed on the basis of patient history and classic clinical findings, such as Tinel's sign (tapping over the median nerve on the volar aspect of the wrist) and results of Phalen's test (the wrist flexion test).⁸⁴ It is important to examine patients for possible motor weakness caused by median nerve compression; electromyography/nerve conduction velocity (EMG/NCV) testing can confirm the diagnosis of CTS in uncertain cases, helping to localize the site of nerve entrapment. In any case, management of CTS is the same for diabetic patients as for nondiabetic patients.

Shoulder

The most common shoulder involvement in diabetes occurs as adhesive capsulitis, or frozen shoulder, which has been reported in 19% of diabetic patients.⁸⁵ *Adhesive capsulitis* refers to a stiffened glenohumeral joint, usually caused by a reversible contraction of the joint capsule; patients report shoulder stiffness, along with decreased range of motion.⁸⁵ *Calcific shoulder periarthritis (tendinitis)* occurs at least three times more frequently than in people without DM and most commonly affects the shoulder in which calcium hydroxyapatite crystals deposit, predominantly in periarticular areas.⁸⁶ Shoulder radiographs show calcium deposits outside of the joint, often in the area of the rotator cuff tendons; however, in up to 60% of cases, this condition is asymptomatic in DM.

Reflex sympathetic dystrophy, also known as *shoulder-hand syndrome* or *complex regional pain syndrome (CRPS)*, has been reported in diabetic patients, although whether it occurs with increased frequency is controversial, and it may be associated with adhesive capsulitis (with or without calcific periarthritis).⁸⁷ Patients describe pain from shoulder to hand in the affected limb, and classic symptoms include swelling of the affected limb/area, skin changes (changes in hair growth, shiny skin, color and temperature changes), increased sensitivity to temperature and touch (hyperesthesia), and vasomotor instability. Transient, patchy osteoporosis may be seen.⁸⁷

Feet

Diabetic osteoarthropathy (also known as *Charcot's* or *neuropathic arthropathy*) is a condition involving destructive, lytic joint changes that most commonly affect the pedal bones.⁸⁸ It presents as a severe, destructive form of degenerative arthritis caused by loss of sensation (brought on by underlying diabetic neuropathy) in involved joints, leading to inadvertent (often unappreciated) repeated microtrauma to the joints with consecutive degenerative changes. Diabetic osteoarthropathy is rare, affecting only 0.1% to 0.4% of diabetic patients, and is seen in both type 1 and type 2 diabetes.⁸⁹ The average duration of Charcot's arthropathy in affected patients is 15 years, and physical examination reveals peripheral neuropathy. Additional symptoms include skin changes such as erythema, swelling, hyperpigmentation, or purpura and soft tissue ulcers over the affected area, as well as joint loosening or instability and joint deformities. The diagnosis is made on the basis of radiographic findings, with symptoms often milder than would be expected from a view of the radiographs. Usually, no history of overt trauma is reported. Depending on the stage and severity of Charcot's arthropathy, radiographs can show degenerative changes with subluxation, bone fragments, osteolysis, periosteal reaction, deformity, and/or ankylosis.

Computed tomography (CT) scans are insensitive in evaluating disease activity, whereas magnetic resonance imaging (MRI) and bone scintigraphy studies are valuable adjuncts to plain films in this regard. Diabetic peripheral neuropathy is thought to play the greatest pathogenic role in diabetic osteoarthropathy. Differential diagnosis includes inflammatory and degenerative processes, infections,

tumors, deep venous thrombosis or thrombophlebitis, and neuropathic arthropathies secondary to other conditions.

Muscles

Diabetic muscle infarction is a rare condition characterized by spontaneous infarction with no history of trauma that tends to affect patients with a long history of poorly controlled DM.⁹⁰ It is seen more frequently in patients with insulin-requiring diabetes, and most affected patients show multiple microvascular complications (e.g., neuropathy, nephropathy, retinopathy). The condition is characterized by an acute onset of pain and swelling over days to weeks in affected muscle groups (usually the thigh or calf), along with varying degrees of tenderness; creatinine phosphokinase levels may be normal or elevated.⁹⁰ However, laboratory investigations need to exclude other conditions such as tumor, muscle infection/abscess, thrombophlebitis/thrombosis, localized myositis, and osteomyelitis. CT scans are nonspecific, and MRI may show high signals of the involved muscle on T2-weighted images.⁹¹

Incisional muscle biopsy may be needed to confirm the diagnosis; primary findings on biopsy include muscle edema and necrosis. Because excisional muscle biopsy may worsen the muscle lesion, this procedure should be done only to rule out infection or malignancy. If such a biopsy is performed, it is important that tissue is sent for culture, and that consideration is given to the presence of atypical organisms and of mycobacteria.

Diffuse Skeletal Disease

Diffuse idiopathic skeletal hyperostosis (DISH) is characterized by metaplastic calcification of spinal ligaments (diagnosed on lateral spine radiographs), along with osteophyte formation.⁹² However, disk spaces, apophyseal joints, and sacroiliac joints are spared, and the thoracic spine is most commonly affected. DISH may be accompanied by more generalized calcification of other extra-axial ligaments and tendons⁹² (Figure 121-1). The underlying pathophysiology

Figure 121-1 Diffuse idiopathic skeletal hyperostosis (DISH): lumbar spine. This lateral radiograph of the lumbar spine shows early changes of DISH. Calcifications of the anterior longitudinal spinal ligament (arrows) are evident and will eventually evolve into flowing osteophytes extending across multiple spinal levels.

is unclear; however, DISH clearly has greater prevalence among diabetic patients than among people without diabetes, particularly in association with type 2 diabetes, and in obese patients.⁹² Classically, patients complain of stiffness in the neck and back with decreased range of motion, and pain generally is not a prominent symptom.

Musculoskeletal Syndromes in Malignancy

ELIZA F. CHAKRAVARTY

KEY POINTS

Musculoskeletal and rheumatic syndromes can occasionally be the first presentation of an underlying malignancy. Older age of onset, prominent constitutional symptoms, atypical features of rheumatic disease, and absence of response to glucocorticoids or other conventional therapy may be suggestive of a paraneoplastic process.

Data from numerous cohorts have confirmed an elevated (>threefold) incidence of malignancy associated with dermatomyositis, including clinically amyopathic dermatomyositis and, to a lesser extent, polymyositis. Solid organ tumors, including lung, colon, and ovarian tumors in European populations and nasopharyngeal tumors in Asian populations, are among the most commonly found tumors in dermatomyositis patients; most malignancies are diagnosed within 1 year of diagnosis of myopathy.

Although to a lesser magnitude than dermatomyositis, investigators in several large population-based studies have found polymyositis to be associated with an increased incidence of malignancy.

Chronic autoimmune conditions such as Sjögren's syndrome, rheumatoid arthritis, and systemic lupus erythematosus are associated with increased risk for the development of lymphoid malignancies compared with the general population. This is believed to be due, at least in part, to chronic inflammation and immune stimulation.

Patients with systemic sclerosis are at increased risk for the development of solid organ tumors primarily involving tissues affected by the fibrotic process.

Musculoskeletal syndromes may be associated with malignancy in a variety of ways. Cause and effect are difficult to define clearly in many situations, however. Certain chronic rheumatic diseases have been associated with increased risk of the subsequent development of malignancy; one example is lymphoma in an individual with primary Sjögren's syndrome. The converse situation also exists, in that certain rheumatic diseases, such as dermatomyositis, are seen more frequently in the presence of an underlying malignancy. Little is understood regarding the pathogenesis of connective tissue disease in association with neoplastic disease. Other factors can contribute to the association of musculoskeletal syndromes and malignancy. Many of the medications used to treat rheumatic diseases modulate the immune system and may be associated directly or indirectly with increased risk for the subsequent development of malignancy. In unusual circumstances, musculoskeletal involvement occurs as a paraneoplastic process, defined

as a hormonal, neurologic, hematologic, or biochemical disturbance associated with malignancy, but not directly related to invasion by the neoplasm or its metastases.¹

PARANEOPLASTIC SYNDROMES

Musculoskeletal syndromes can develop as a manifestation of a paraneoplastic process and occasionally can be the first presentation of an underlying malignancy. Hematologic malignancies, lymphoproliferative disorders, and solid tumors are associated with a wide variety of paraneoplastic rheumatic syndromes. Older age of onset, atypical features of rheumatic disease, and absence of response to glucocorticoids or other conventional therapy may suggest a paraneoplastic process. Knowledge of the associations with rheumatic syndromes and underlying malignancy is crucial when caring for these patients. Hypertrophic osteoarthropathy, amyloidosis, and secondary gout are reviewed in Chapters 102, 116, 94, and 95. [Table 122-1](#) lists common paraneoplastic associations.

Carcinomatous Polyarthrititis

The term *carcinomatous polyarthrititis* is used to describe the development of arthritis in association with malignancy, but it is distinct from arthritis associated with metastasis or direct tumor invasion. [Table 122-2](#) lists common features of carcinomatous polyarthrititis. It generally occurs in patients who are older; it has an explosive onset and often develops in close temporal correlation with discovery of the malignancy. Although it can have various presentations and may mimic the appearance of rheumatoid arthritis (RA)² or asymptomatic migratory polyarthrititis,³ carcinomatous polyarthrititis is more often a seronegative asymmetric disease with predominant involvement of the lower extremities and some sparing of the small joints of the hands. No evidence of direct tumor extension or metastasis has been found, and no specific histologic or radiographic appearance has been identified. Carcinomatous polyarthrititis can occur in association with many types of malignancy, but has been reported in greatest frequency in association with breast, colon, lung, and ovarian cancers and with lymphoproliferative disorders.⁴ The underlying pathogenesis of this process has not been elucidated; however, the arthritic symptoms may be improved with successful treatment of the malignancy.⁵

Vasculitis

Vasculitis in association with malignancy is uncommon and has a reported prevalence of only 8% among patients with malignancy.⁶ The association seems to be significantly

Table 122-1 Paraneoplastic Syndromes

Connective Tissue Disease	Malignancy	Clinical Setting	Clinical Alert
Carcinomatous polyarthritis	Multiple types of solid tumors, including breast; lymphoproliferative disorders	See Table 122-2	See Table 122-2
Vasculitis	Lymphopoietic and hematopoietic malignancies	Cutaneous vasculitis most common; systemic vasculitis rare	Vasculitis not related to infections, medications, or autoimmune disease
Mixed cryoglobulinemia	Non-Hodgkin's lymphoma	Immune complex-mediated disease with cutaneous vasculitis, neuropathy, fatigue, and visceral organ involvement	Usually appears 5-10 yr after diagnosis of cryoglobulinemia
Panniculitis	Hematologic malignancies; pancreatic, breast, and prostate cancers	Induration of skin and deeper tissues; eosinophilia often present	Usually refractory to prednisone
Fasciitis	Ovarian, breast, gastric, and pancreatic cancers	Palmar fasciitis with inflammatory polyarthritis; similar in presentation to reflex sympathetic dystrophy	Bilateral presentation; severe fibrosis and contractures; aggressive course
Reflex sympathetic dystrophy syndrome	Multiple cancer types; Pancoast tumors	Tumors may invade stellate ganglion or brachial plexus on affected side	Absence of typical antecedent factors; failure to respond to conventional therapies
Erythromelalgia	Myeloproliferative disorders	Often seen in setting of thrombocytosis	—
Atypical polymyalgia rheumatica	Renal, lung, and colon cancer; multiple myeloma	—	Age <50 yr; asymmetric involvement; poor response to prednisone
Digital necrosis	Gastrointestinal and pulmonary tumors	Severe Raynaud's phenomenon with onset >50 yr old	Asymmetric features; digital necrosis
Remitting seronegative symmetric synovitis with pitting edema	Several tumor types	Abrupt onset of arthritis and edema surrounding wrists and small joints of hands	Presence of fever, weight loss; poor response to prednisone
Multicentric reticulohistiocytosis	Lung, stomach, breast, cervix, colon, and ovarian carcinomas	—	—
Lupus-like syndromes	Variety of solid tumors and lymphoproliferative disorders	—	Rare associations with malignancy limited to case reports
Antiphospholipid antibodies	Multiple cancer types	Association between antibodies, cancer, and risk of thrombosis unclear	Higher presence of antibodies found in patients with malignancy
Osteogenic osteomalacia	Solid tumors and tumors of mesenchymal origin	Bone pain and muscle weakness	Diligent search is indicated in all patients with late-onset apparent idiopathic osteomalacia
Sarcoidosis	Cervical, bladder, gastric, lung, breast, and renal cancers and cutaneous and pulmonary squamous cell carcinomas	Highest incidence of "malignancy" during first 4 yr after detection of granulomata	Malignant tumors can cause sarcoid-like tissue reactions leading to mistaken diagnosis of sarcoidosis before recognition of malignancy
Lymphomatoid granulomatosis	Lymphoma	Unusual granulomatous form of vasculitis with angi-destructive infiltration of various tissues	—

Table 122-2 Features of Carcinomatous Polyarthritis

Close temporal relationship between onset of arthritis and discovery of malignancy
Late age of onset of arthritis
Asymmetric joint involvement
Explosive onset
Predominant lower extremity involvement with sparing of wrists and small joints of hands
Absence of rheumatoid nodules
Absence of rheumatoid factor
No family history of rheumatoid disease
Nonspecific histopathologic appearance of synovial lining
No periosteal reaction

higher with lymphoproliferative and myeloproliferative disorders than with solid tumors, and vasculitis commonly predates the identification of malignancy. The vasculitic process is most often small vessel and cutaneous and only rarely involves significant organs. Up to 5% of patients with cutaneous vasculitis have an underlying neoplasm.⁷ Treatment often requires the use of glucocorticoids and therapy directed against the underlying malignancy, although it seems that this is often ineffective. Table 122-1 shows malignancies associated with vasculitis. In the setting of malignancy, it is believed that persistent antigen stimulation from the tumor results in T cell activation or immune complex formation and deposition.

The development of small vessel vasculitis has been reported to antedate and postdate the development of lymphoproliferative and myeloproliferative diseases. One group looked retrospectively at 222 patients with vasculitis and identified 11 who had developed an associated malignancy.⁸ Of these 11 patients, 7 had hematologic neoplasia, and 4 had malignant solid tumors. Nine of the patients manifested cutaneous vasculitis, and the remaining 2 had vasculitic involvement in the bowel. In 4 patients, the development of vasculitis antedated the diagnosis of malignancy.⁸ Similar findings were reported by investigators, who found an underlying malignancy in 8 of 192 patients with cutaneous vasculitis. Most malignancies were hematologic (6 of 8) and predated (5 of 8) the diagnosis of cancer.⁹ In a retrospective analysis of 23 patients with cutaneous vasculitis and hematologic malignancies, the authors were able to attribute the presence of vasculitis to the malignancy itself in 61% of cases.¹⁰

Systemic vasculitis is much less commonly associated with underlying malignancy. Case reports and small series have found antineutrophil cytoplasmic antibody (ANCA)-negative and ANCA-positive vasculitis associated with hematologic malignancies.¹¹⁻¹³ Granulomatosis with polyangiitis (GPA) (formerly Wegener's granulomatosis) has likewise been associated with the development of several types of malignancies, including lymphoproliferative disorders, bladder cancer, and renal cell carcinoma.^{14,15} In some cases, the malignancy was diagnosed within months of the diagnosis of GPA,¹⁴ and in other reports, cancer developed many years after diagnosis and treatment of vasculitis,¹⁵ making it unclear whether the malignancies were a result of the vasculitis or possibly the treatment. A group from the Cleveland Clinic did a retrospective study to assess directly the temporal relationship between vasculitis and cancer.¹⁶ During an 18-year study period, the authors found only 12 cases of vasculitis and cancer diagnosed within the same 12-month period: Six patients had lymphoproliferative disorders, and 6 had solid tumors. In most cases, the vasculitis responded partially to immunosuppressive therapy, but investigators observed a more impressive improvement in vasculitis with definitive treatment for the underlying malignancy. A more recent study found 20 cases of malignancy among 200 patients with ANCA-positive vasculitis; 6 were diagnosed concurrently with a diagnosis of vasculitis, and 14 predated vasculitis by a median of 96 months.¹⁷ Only 4 of 20 malignancies in this series were lymphoproliferative; the remaining malignancies were solid organ tumors.

Vasculitis associated with underlying malignancy is often poorly responsive to conventional therapy directed against the vasculitis. In one series of 13 patients with cutaneous vasculitis and lymphoproliferative or myeloproliferative disorder, symptoms of vasculitis were poorly responsive to therapy with nonsteroidal anti-inflammatory drugs (NSAIDs), glucocorticoids, antihistamines, and antiserotonin agents. Although investigators described lessening of the severity of vasculitis after chemotherapy directed against the malignancy, they generally found chemotherapy to be ineffective. Of 13 patients identified, 10 died as a direct result of the malignancy.¹⁸ Similarly, Hutson and Hoffman¹⁶ found general concurrence between improvement in vasculitic syndrome and definitive treatment for the associated underlying malignancy. More recently, a study of cutaneous

small vessel vasculitis associated with solid tumors (most commonly lung, breast, and prostate) found a significant response to immunosuppressive therapy directed against the vasculitis, although concurrent treatments for the underlying malignancy were undertaken.¹⁹

Cryoglobulinemia

Cryoglobulins are immunoglobulins that precipitate at reduced temperature. Cryoglobulinemia can be characterized by hyperviscosity symptoms or by vasculitis. Patients often have fatigue, arthralgia or arthritis, cutaneous vasculitis or purpura, neuropathy, digital ischemia, and visceral organ involvement (renal or pulmonary). Three types of cryoglobulins have been identified:

Type I: Monoclonal immunoglobulin, either IgG or IgM; this type is associated with lymphoproliferative disorders.

Type II: Monoclonal IgM directed against polyclonal IgG; type II cryoglobulins were initially thought to be idiopathic and were known as mixed essential cryoglobulinemia. With the identification of hepatitis C virus (HCV), it has been discovered that most of these patients have HCV infection that is directly involved in the pathogenesis of the cryoglobulins. Specific epitopes of HCV antigens are recognized by IgG components of immune complexes, and viral particles are found in the cryoprecipitate.²⁰ One study found clonal B cell populations in the peripheral blood of 48% of HCV-positive patients with type II cryoglobulinemia, many of whom were eventually diagnosed with a B cell malignancy.²¹ Overall, it is estimated that approximately 5% to 8% of patients with mixed cryoglobulinemia may go on to develop non-Hodgkin's lymphoma, usually after 5 to 10 years of cryoglobulinemia.^{22,23} The risk of developing non-Hodgkin's lymphoma among HCV-positive cryoglobulinemic patients may be 35 times higher than in the general population.²⁴ Other data suggest that HCV infection may be associated with other hematologic malignancies.^{25,26} At this time, the subset of patients with mixed cryoglobulinemia who will develop lymphoma cannot be predicted.

Type III: Mixed polyclonal IgG and IgM; type III cryoglobulins are commonly seen with a variety of illnesses, including connective tissue diseases (systemic lupus erythematosus [SLE] and RA) and infections. In one study of 607 patients diagnosed with mixed cryoglobulinemia, 27 cases of hematologic malignancy were identified. Of these, systemic autoimmune diseases were detected in 56% of cases of non-Hodgkin's lymphoma.²⁶

Panniculitis

The fasciitis-panniculitis syndrome, which includes eosinophilic fasciitis, is characterized by swelling and induration of the skin that extends into deeper subcutaneous tissues and is associated with fibrosis and chronic inflammation. Patients may develop arthritis and subcutaneous nodules similar to those seen in erythema nodosum. The arthropathy seems to be secondary to periarticular fat necrosis, can

be monoarticular or polyarticular,²⁷ and may mimic RA or juvenile RA.²⁸ Blood and tissue eosinophilia is commonly, but not always, present.²⁹ This syndrome can be idiopathic and have a benign course, or it can be secondary to a variety of infectious, vascular, or traumatic events. In a few patients, the fasciitis-panniculitis syndrome is associated with an underlying malignancy. Hematologic malignancies are most often associated with this syndrome and are usually diagnosed concurrently or within the first year.^{30,31} Pancreatic cancer and pancreatitis also can be associated with this syndrome.^{27,28} Patients with cancer-associated fasciitis-panniculitis syndrome are predominantly female and are generally refractory to prednisone.²⁹

Palmar Fasciitis

Palmar fasciitis with arthritis is a syndrome characterized by progressive bilateral contractures of the digits, fibrosis of the palmar fascia, and inflammatory polyarthritis.^{32,33} The metacarpophalangeal and proximal interphalangeal joints are most commonly affected; other affected joints include the elbows, wrists, knees, ankles, and feet. Indurated reticulate palmar erythema can also be seen as part of the palmar fasciitis spectrum.³⁴ Palmar fasciitis is almost uniformly associated with the presence of an underlying malignancy, most often ovarian, breast, gastric, and pancreatic tumors.^{33,35,36} Although initially thought to be an atypical variant of reflex sympathetic dystrophy, the severity of manifestations, bilateral presentation, and strong association with occult malignancy suggest that, in these cases, palmar fasciitis is a distinct entity that behaves as a paraneoplastic syndrome. Glucocorticoids, chemotherapy, or both do not seem to result in improvement, although fasciitis occasionally regresses with treatment of the underlying malignancy.³²

Reflex Sympathetic Dystrophy

Reflex sympathetic dystrophy and a variant, shoulder-hand syndrome, are characterized by regional pain, swelling, vasomotor instability, and focal osteoporosis in a given limb; this condition is thought to be caused by sympathetic dysfunction. Absence of associated antecedent factors, such as stroke, myocardial infarction, or trauma, and failure to respond to conventional therapy warrant a search for an underlying malignancy. A variety of malignancies have been associated with the development of reflex sympathetic dystrophy or its variants.^{37,38} Pancoast tumor of the lung apices and other malignancies that infiltrate the stellate ganglion or brachial plexus have been described in patients with reflex sympathetic dystrophy.³⁹⁻⁴¹ Therapy directed against the underlying malignancy may lead to some amelioration of symptoms associated with reflex sympathetic dystrophy.

Erythromelalgia

Erythromelalgia is an enigmatic condition characterized by attacks of severe burning, erythema, and warmth of the extremities with symptoms predominantly involving the feet.^{42,43} Symptoms are often exacerbated when the extremities are placed in a dependent position, during ambulation, or during exposure to increased temperatures. Partial relief

can be obtained through elevation or cooling of the extremity. This disorder can occur idiopathically (60%) or secondary to another disease (40%).^{42,44} Myeloproliferative disorders, including polycythemia vera and essential thrombocytosis, are common primary causes and have been found to precede the diagnosis of erythromelalgia by several years.^{7,43,45} The underlying pathophysiology of this disease is unknown; however, it is often associated with thrombocytopenia. In the largest published retrospective cohort, 168 patients at the Mayo Clinic were identified with this diagnosis between 1970 and 1994.⁴⁶ The authors found that after a mean follow-up of 8.7 years, 31.9% of patients reported worsening of disease, 26.6% reported no change, 30.9% reported improvement, and 10.6% reported complete resolution of symptoms. Kaplan-Meier survival curves revealed a significant decrease in survival compared with controls. A history of myeloproliferative disease was found in 15 of 168 patients. The exact cause of the symptoms is unclear, but microvascular arteriovenous shunting has been hypothesized.⁴⁷ In cases of secondary erythromelalgia, platelet breakdown products and platelet microthrombi may underlie disease pathogenesis.⁷ The most effective therapy seems to be the use of daily aspirin, leading to significant relief of symptoms, which is believed to be related to inhibition of cyclooxygenase-1. A host of other therapies have been tried with varying success.⁴⁸ Because of the association with myeloproliferative diseases, routine monitoring with complete blood counts is prudent.

Polymyalgia Rheumatica

Polymyalgia rheumatica is a disorder affecting older adults that manifests with discomfort and stiffness in the shoulder and hip girdle, fatigue, anemia of chronic disease, and elevated erythrocyte sedimentation rate (ESR). Classically, this condition responds to moderate doses of prednisone within 48 hours. A variety of other conditions can have presentations that mimic polymyalgia rheumatica, including other rheumatic disorders, systemic infections, and malignancy.⁴⁹ Although the association between polymyalgia rheumatica and malignancy has been controversial, atypical features of polymyalgia rheumatica may suggest the presence of occult malignancy, including age younger than 50 years, limited or asymmetric involvement of typical sites, ESR less than 40 mm/hr or greater than 100 mm/hr, severe anemia, proteinuria, and poor or delayed response to 20 mg daily of prednisone. Kidney, lung, and colon cancer and multiple myeloma are most often found in patients presenting with atypical polymyalgia rheumatica.⁵⁰⁻⁵² One study of patients undergoing evaluation for possible polymyalgia rheumatica found 10% to have a diagnosis of malignant neoplasms.⁵³ In contrast, several prospective studies have shown that patients who present with classic polymyalgia rheumatica or temporal arteritis do not seem to have an increased risk of developing malignancy over age-matched controls.⁵⁴⁻⁵⁸

Raynaud's Phenomenon and Digital Necrosis

The development of digital necrosis or profound Raynaud's phenomenon may suggest the presence of infection, inflammatory disease, or an underlying malignancy. In patients

older than 50 years, the development of Raynaud's phenomenon, particularly in an asymmetric fashion or in association with digital necrosis, should raise the possibility that this is a paraneoplastic process. These features often antedate the diagnosis of the malignancy by an average of 7 to 9 months.^{59,60} A variety of solid tumors and lymphoproliferative disorders have been associated with this syndrome.^{59,65} Certainly, the presence of digital necrosis in patients with dermatomyositis is highly suggestive of the presence of an underlying malignancy. Mechanisms proposed include cryoglobulinemia, immune complex-induced vasospasm, hypercoagulability, marantic endocarditis with emboli, and necrotizing vasculitis.⁶⁵ Therapy with interferon- α also has been reported in association with the development of Raynaud's phenomenon and digital necrosis.⁶⁶⁻⁶⁸

Remitting Seronegative Symmetric Synovitis with Pitting Edema

Remitting seronegative symmetric synovitis with pitting edema (RS₃PE) is an uncommon disorder primarily affecting the metacarpophalangeal joints and the wrists. Although the underlying cause and pathogenesis of this illness are unclear, lymphoma, myelodysplastic syndromes, and several solid tumors, mostly adenocarcinoma, all have been reported in association with it.⁶⁹⁻⁷³ One retrospective study from a single center in the United States found that 3 of 14 patients with RS₃PE developed cancer.⁷⁴ Characteristics that suggest possible underlying malignancy include the presence of systemic features, such as fever or weight loss, and a poor response to glucocorticoids.^{71,72}

Multicentric Reticulohistiocytosis

Multicentric reticulohistiocytosis is a rare condition characterized by the presence of cutaneous papules often associated with a destructive arthritis of the interphalangeal joints of the hands. The papules are flesh-colored to brown-yellow and are classically present in the periungual region and on the dorsal hands and face. Arthritis mutilans may develop in 50% of cases. The characteristic histologic appearance of tissue infiltration with histiocytes and multinucleated giant cells can be found in affected skin, joints, and occasionally internal organs.⁷⁵ Multicentric reticulohistiocytosis has been reported in association with hyperlipidemia, malignancies, and autoimmune diseases. Malignancy has been associated in 25% to 31% of cases, although most literature consists of individual case reports.^{76,77} The most frequently seen malignancies include carcinoma of the lung, stomach, breast, cervix, colon, and ovary.⁷⁵

Lupus-like Syndromes

Lupus-like syndromes are rarely associated with underlying malignancy. Isolated case reports have described lupus-like syndromes with ovarian carcinoma^{78,79} and hairy cell leukemia⁸⁰; subacute cutaneous lupus was reported in a patient with breast carcinoma.⁸¹ Studies on the presence of antinuclear antibodies (ANAs) in patients with cancer have yielded mixed results. Two studies were unable to find a

significantly increased prevalence of ANAs in patients with solid tumor or lymphoma compared with healthy controls.^{82,83} In contrast, one smaller study found an increased prevalence in patients with non-Hodgkin's lymphoma compared with controls (21% vs. 0),⁸⁴ and another study found a prevalence of ANAs of 27.7% in 274 patients with various malignancies compared with 6.45% of 140 healthy controls.⁸⁵ No predictive features seem to suggest occult malignancy in patients presenting with lupus-like syndromes or positive ANAs.

Antiphospholipid Antibodies

Antiphospholipid antibodies and their association with thromboses have been described as a primary syndrome and a secondary phenomenon in autoimmune diseases, primarily SLE. More recently, antiphospholipid antibodies have been associated with a variety of malignancies. Correlations between antiphospholipid antibodies in cancer patients and thromboembolic events have been less clear, however.

Several studies have shown the presence of antiphospholipid antibodies in patients with solid tumors and lymphoproliferative disorders at a higher frequency than the 1% to 5% seen in the general population.^{86,87} An early study of 216 consecutive patients with cancer found 22% positive for anticardiolipin antibodies compared with 3.4% in controls. This study found a two-fold increase in the development of thromboembolism in patients with positive antibodies compared with patients with negative serologies; it also indicated that most thromboembolic events occurred in patients with higher antibody titers.⁸⁸ Other studies have confirmed the association between malignancy and antiphospholipid antibodies (12.5% to 68%), but have been unable to show a correlation with thromboembolic events.^{84,86,89-93} A correlation between antibody titer and disease activity has been shown in some studies,^{81,83} and decreased survival in others.^{93,94} A review of the literature concluded that antiphospholipid antibodies resolve in one-third of cancer patients after treatment for the underlying malignancy.⁹⁵

Studies of the prevalence of antiphospholipid antibodies in unselected patient populations have shown an association with underlying malignancy. A prospective study in France found that 7% of 1014 consecutive patients admitted to a medical ward had antiphospholipid antibodies.⁹⁶ In antibody-positive patients, cancer was the most frequently associated disease. A more recent study in patients presenting with a first ischemic stroke found a significantly higher rate of development of cancer within 12 months in patients who had anticardiolipin antibodies (19% vs. 5%).⁹⁷

Osteomalacia

Osteomalacia is the softening of bones often associated with failure of adequate calcification secondary to renal dysfunction or to lack of vitamin D. Osteomalacia has been associated with benign and malignant solid tissue and mesenchymal tumors.⁹⁸ Tumors causing oncogenic osteomalacia have been shown to overproduce fibroblast growth factor 23 (FGF-23), and elevated serum levels of FGF-23 can be detected in patients with this paraneoplastic condition.^{99,100} Octreotide scintigraphy may be a useful tool for

identifying occult tumors.¹⁰¹ With removal of the tumor, there often seems to be resolution of the osteomalacia and normalization of serum FGF-23 levels.¹⁰⁰

Sarcoidosis

Noncaseating granulomata can occur in numerous settings and are not pathognomonic for sarcoidosis. Granulomata resembling those of sarcoidosis may be found in lymph nodes that drain sites of malignancy. These tumor-related tissue reactions resulting in granuloma formation have been described with many types of malignant lesions, including solid tumors and lymphomas.^{102,103} The clinical and radiographic presentation of sarcoidosis and cancer can be virtually indistinguishable, making it important to pursue aggressive evaluation in a patient with sarcoidosis.^{104,105}

The risk of malignancy developing in patients with an established diagnosis of sarcoidosis is controversial. Some studies have shown an increased risk of developing lung cancer and lymphoma,¹⁰⁶⁻¹⁰⁸ whereas others have shown no increased risk of cancer over the general population.^{104,109,110}

Lymphomatoid Granulomatosis

Lymphomatoid granulomatosis is a rare disorder with angiodestructive and lymphoproliferative features involving the lung and, less often, the skin and central nervous system. Although lymphocytic infiltration of vessels is a hallmark of the disease, lymphomatoid granulomatosis now seems to fall within the spectrum of lymphoproliferative disorders.¹¹¹ Despite the predominance of T cells within inflammatory infiltrates, studies have suggested that an Epstein-Barr virus (EBV)-associated B cell proliferation may underlie the pathogenesis of the disease.^{112,113} Prognosis is generally poor, with a median survival from diagnosis of 14 months,¹¹⁴ although more recent reports suggest some response to rituximab therapy.^{115,116} Frank lymphomas evolve in 25% of cases.¹¹⁷

INFLAMMATORY MYOPATHIES

The inflammatory myopathies in adult populations encompass a group of illnesses characterized by an idiopathic immune-mediated attack on skeletal muscle resulting in muscle weakness. Many associations between the inflammatory myopathies and the presence of malignancy have been noted, but the reason for the association remains unknown.¹¹⁸ Dermatomyositis has classically been associated with occult malignancies, whereas associations between polymyositis and inclusion body myositis are becoming increasingly recognized. A further issue is whether the inflammatory myopathy predates the malignancy and can be considered a primary rheumatic disease with known risks of developing malignancy, or whether it simply represents a manifestation of a paraneoplastic process.

On average, the prevalence of malignancy in association with inflammatory myopathies has been approximately 15% to 25%, which appears to be consistent across populations studied. The frequency of malignancy has ranged, however,

from 6% to 60% in patients with dermatomyositis, and from 0 to 28% in patients with polymyositis.^{118,119} Other estimates have placed the incidence of cancer in patients with inflammatory myopathies at five to seven times that of the general population.¹¹⁸

Dermatomyositis has been associated with a wide range of malignancies; solid tumors are most often seen in cancer-associated myositis as opposed to lymphoid malignancies. Ovarian, lung, and gastric tumors are most common in European populations, and nasopharyngeal malignancies in Asian populations. Studies have confirmed a strong association between dermatomyositis and malignancy. Hill and colleagues¹²⁰ studied a pooled cohort of patients from Sweden, Denmark, and Finland and found 198 cases of cancer in 618 patients with dermatomyositis. The standardized incidence ratio (SIR) for malignancy with dermatomyositis was 3. Similar results were found in a Scottish cohort of 286 patients with dermatomyositis.¹²¹ Of these patients, 77 were found to have underlying malignancies, with an SIR of 3.3 to 7.7. Buchbinder and co-workers¹²² used strict histopathologic criteria to classify myositis in patients from Victoria, Australia. This group found 36 cases of cancer in 85 patients diagnosed with dermatomyositis and an SIR of 4.3 to 6.2. All of these studies have suggested that cancers are most commonly diagnosed within 1 to 2 years of diagnosis of dermatomyositis.

In contrast to previous work, studies of Asian populations have shown a higher association of nasopharyngeal carcinomas with dermatomyositis. In a nationwide Taiwanese study, 9.4% of 1012 patients with dermatomyositis were found to have an underlying malignancy, the most common of which was nasopharyngeal cancer, followed by lung cancer.^{123,124} In a smaller study, 66.6% of 15 dermatomyositis patients in Singapore had malignancies, most of which were nasopharyngeal carcinoma.¹²⁵ Eight white patients with nasopharyngeal carcinoma within 1 year of diagnosis of dermatomyositis were reported more recently in Tunisia.¹²⁶ A similar study from Japan found that cancer was diagnosed in 24% of dermatomyositis patients; most cases involved gastric cancer, a common malignancy in the Japanese population.¹²⁷

In polymyositis, the relative risk for developing internal malignancies seems to be lower than that for dermatomyositis, but it is consistently increased over that expected in the general population. Studies have found a 14% to 30% prevalence of cancer among patients with polymyositis, with SIRs increased to 1.2 to 2.1.¹²⁰⁻¹²³ The nationwide Taiwanese study found a 4.4% incidence of cancer among 643 patients with polymyositis, with an SIR of 2.15 compared with the general population.¹²⁴ Small numbers of many types of cancers were found. These studies confirm results reported in previous large studies of Swedish and Finnish populations and a 1994 meta-analysis of all published case-control and cohort studies of malignancy and myositis, which identified an odds ratio for the association of cancer with dermatomyositis of 4.4, and of cancer with polymyositis of 2.1.¹²⁸

In amyopathic dermatomyositis, a variant of dermatomyositis in which typical cutaneous manifestations are present with subclinical or no identifiable muscle disease, the association with underlying malignancy is now

becoming clear. Whereas previous published reports were limited to small groups of patients,^{125,129-131} recently published cohort studies and a systematic review of the amyopathic dermatomyositis literature have suggested similar associations between amyopathic dermatomyositis and internal malignancies.^{127,132,133}

Far less is known about the association of inclusion body myositis with underlying malignancy. In Buchbinder's study from Northern Europe, 52 patients were identified with inclusion body myositis.¹²² Of these patients, 12 were found to have internal malignancies, with an SIR of 2.4. The numbers of each type of cancer seen are too small to reveal specific associations.¹⁰⁷

Not all studies concur regarding the association between the inflammatory myopathies and malignancy.^{134,135} In a study done at the Mayo Clinic, patients with myositis did not seem to be at statistically significant risk for the development of malignancy. No clinical differences were seen between patients who developed a malignancy and patients who did not.¹³⁵

Despite the negative results of some studies, it seems that most work supports the notion of an increased risk of malignancy in association with dermatomyositis and polymyositis. For patients in whom an inflammatory myopathy has been diagnosed, a workup for the presence of malignancy should be done. The extent of this workup has been debated, however, because extensive undirected searches often result in a very low yield. It is probably rare for an undirected workup to yield evidence of malignancy in polymyositis and dermatomyositis patients¹³⁶; any workup should be tailored to the individual patient's age, symptoms, and signs. Studies have suggested that imaging of the chest, abdomen, and pelvis may increase the potential for discovery of underlying malignancy.^{137,138} Other studies have suggested the use of serum tumor markers (CA125 and CA19-9) to augment detection of patients with dermatomyositis or polymyositis at highest risk for associated malignancy.¹³⁹ More recently, a prospective study of whole body positron emission tomography (PET)/computed tomography (CT) was found to be comparable with broad conventional screening (including chest, abdominal, and pelvic CT scans, among other tests).¹⁴⁰ Malignancies associated with inflammatory myopathies have been known to develop many years after the diagnosis of muscle disease, so continued vigilance and repeated screening for malignancy are warranted.

In certain cohorts, the risk of malignancy may be higher, including those with older age at diagnosis,¹⁴¹ evidence of distal extremity weakness,¹⁴² and prominent pharyngeal and diaphragmatic involvement.¹⁴² Patients with myositis-associated autoantibodies may be at less risk for the development of malignancy.¹⁴²⁻¹⁴⁴ More recent work has suggested that the presence of leukocytoclastic vasculitis¹⁴⁵ and cutaneous ulceration,¹⁴² as well as the absence of pulmonary involvement,¹⁴¹ increases further the possibility that an underlying malignancy is present.

Although the pathogenesis is unknown, the types of malignancy associated with inflammatory myopathies have been varied, including adenocarcinomas of the breast, ovaries, and stomach. Most cases of dermatomyositis and malignancy seem to occur within 1 year of each other, with myositis diagnosed first in most cases.¹¹⁸ When identified, removal of the malignancy may result in improvement of

the myopathic process, which further supports the paraneoplastic nature of myositis in some cases.¹⁴⁶

RISKS OF DEVELOPING LYMPHOPROLIFERATIVE DISORDERS IN RHEUMATIC DISEASES

Since the 1960s, increasing numbers of reports have described the association between rheumatic disease and the development of malignancy, particularly lymphoproliferative disorder. Table 122-3 shows pre-existing connective tissue diseases that have been associated with malignancy. Much of what is known about associations between rheumatic disease and malignancy is drawn from retrospective and prospective cohort studies, registry linkage studies, small series, and case reports. This is thought to be mediated, at least in part, by chronic immune stimulation and hyperactivity that may lead to malignant transformation. In addition, certain confounding factors need to be considered when the risk of development of malignancy is assessed, including the potential oncogenic properties of many of the immunosuppressive and cytotoxic medications prescribed to treat autoimmune diseases. Lymphoproliferative disorders have developed in patients with rheumatic diseases and in recipients of solid organ transplantations treated with immunosuppressive agents. EBV has been implicated in the development of lymphoid neoplasia in immunosuppressed patients. In the following sections, many of the rheumatic diseases and the therapies used to treat them are discussed.

Sjögren's Syndrome

Sjögren's syndrome, an autoimmune exocrinopathy, is characterized by a benign lymphocytic infiltrate of salivary and lacrimal glands that leads to the development of sicca syndrome (keratoconjunctivitis and xerostomia).¹⁴⁷ The development of lymphoproliferative disorders in the setting of Sjögren's syndrome is perhaps the prototypic example of chronic autoimmune disease with increased risk of malignancy. In 1964, investigators first reported the development of four cases of lymphoproliferative disorders in a cohort of 58 patients with Sjögren's syndrome.¹⁴⁸ In 1978, 7 of 136 patients with sicca syndrome were identified as having developed non-Hodgkin's lymphoma. Compared with the expected incidence of cancer among women of the same age range, a 44-fold increased risk of developing non-Hodgkin's lymphoma was noted.¹⁴⁹ These findings have been reproduced numerous times in other cohorts. Lymphoproliferative disorders complicate approximately 4% to 10% of cases of primary Sjögren's syndrome.¹⁵⁰⁻¹⁵⁷ The relative risk for development of lymphoproliferative disorders in patients with primary Sjögren's syndrome ranges from 6 to 44,^{149,158-163} and a meta-analysis of cohort studies has found a pooled SIR of 18.8.¹⁶⁰ Most lymphoproliferative disorders were non-Hodgkin's lymphoma, specifically mucosa-associated lymphoid tissue (MALT) lymphoma, other marginal-zone lymphomas, and diffuse large B cell lymphoma.^{155,156} Waldenström's macroglobulinemia, chronic lymphocytic leukemia, and multiple myeloma were more rarely reported.^{149,153,154,159}

Table 122-3 Pre-existing Connective Tissue Diseases Associated with Malignancy

Connective Tissue Disease	Malignancy	Associated Factors	Clinical Alert
Sjögren's syndrome	Lymphoproliferative disorders	Glandular features: lymphadenopathy, parotid or salivary enlargement Extraglandular features: purpura, vasculitis, splenomegaly, lymphopenia, low C4 cryoglobulins	Clues to progression from pseudolymphoma to lymphoma include worsening of clinical features, disappearance of rheumatoid factor, and decline of IgM
Rheumatoid arthritis	Lymphoproliferative disorders	Presence of paraproteinemia, greater disease severity, longer disease duration, immunosuppression, Felty's syndrome	Rapidly progressive, refractory flare in long-standing rheumatoid disease may suggest an underlying malignancy
SLE	Lymphoproliferative disorders	—	Non-Hodgkin's lymphoma should be considered in SLE patients who develop adenopathy or masses; lymphoma of the spleen is another cause of splenic enlargement in SLE
Discoid lupus erythematosus	Squamous cell epithelioma	Found in oldest plaques, ≥20 yr after onset of discoid lesion, primarily in men 30-60 yr old	Poorly healing skin lesion within discoid plaques should be evaluated
Systemic sclerosis (scleroderma)	Alveolar cell carcinoma	Pulmonary fibrosis, interstitial lung disease	Annual chest radiograph after fibrosis is detected
	Nonmelanoma skin cancer	Areas of scleroderma and fibrosis in the skin	Changes in skin features or poorly healing lesions should be evaluated
	Adenocarcinoma of the esophagus	Barrett's metaplasia	Esophagoscopy and biopsy, if indicated, of distal esophageal constricting lesions
Paget's disease of bone	Osteogenic sarcoma	Development of severe pain; increasing incidence with age	Swelling and bone destruction in pre-existing Paget's disease may be sarcoma; diagnosis may require biopsy
Dermatomyositis	Ovarian, lung, and gastric cancer in Western populations; nasopharyngeal carcinoma in Asian populations	Older age, presence of cutaneous vasculitis; less likely in setting of myositis-specific antibodies or interstitial lung disease	Malignancy evaluation needs to be tailored to individual patient's age, symptoms, and signs

SLE, systemic lupus erythematosus.

Generally, the development of lymphoma is a late manifestation of Sjögren's syndrome, often seen after 6.5 years of disease.^{151,152,164} Clinical and laboratory features seem to be associated with or predictive of development of lymphoproliferative disorders, including palpable purpura,^{148,153,154,163} cutaneous ulcerations,¹⁵⁰ cryoglobulinemia,^{154,155} low serum complement levels,^{153-155,165} monoclonal gammopathies,^{166,167} cytopenias,^{148,155,163} splenomegaly,^{148,155} and adenopathy.¹⁵⁰ Progression to high-grade lymphoma portends a poor prognosis.* In contrast, the incidence of other malignancies or all-cause mortality was not increased in patients with Sjögren's syndrome compared with the general population.^{159,163,164,168} It is believed that chronic B cell stimulation may lead to the malignant transformation of clonal lines characteristic of Sjögren's syndrome.¹⁴⁷ The presence of a viral trigger accounting for malignant transformation is one possible theory. EBV, among other viruses, has been implicated, but studies have failed to find EBV or other viral particles in lymphoma specimens associated with Sjögren's syndrome.¹⁶⁹

Other reports have described the presence of chromosomal translocations with increased frequency in patients

with Sjögren's syndrome who have developed lymphoma. One group of investigators identified the presence of translocations of the proto-oncogene *bcl-2*¹⁷⁰ in 5 of 7 patients with Sjögren's syndrome and lymphoma by the use of polymerase chain reaction. Such translocations were found in peripheral blood or bone marrow in 5% of unselected patients with Sjögren's syndrome without evidence of lymphoma in another study.¹⁷¹ Conversely, no evidence of *bcl-2* translocations was present in 50 salivary gland biopsy specimens of patients with Sjögren's syndrome without evidence of lymphoma.¹⁷² Analysis of biopsy specimens taken before the development of lymphoma from the 7 patients previously mentioned revealed no evidence of *bcl-2* translocation. Translocation seemed to correlate with the development of lymphoma in at least a subset of patients with Sjögren's syndrome, and the use of polymerase chain reaction technology may allow early detection of malignant transformation.¹⁷¹⁻¹⁷³

Rheumatoid Arthritis

Data from numerous studies since the 1970s are persuasive that RA is associated with a twofold to threefold increased risk for the development of lymphoproliferative disorders,

*References 30, 132, 133, 140, 151, 153, 154, 163.

the magnitude of which has remained constant despite dramatic changes in therapy. Many factors, including chronic inflammation and immune dysregulation, in addition to potential oncogenic properties of immunosuppressive therapies for the treatment of RA, must be considered when the risk of development of hematologic malignancies is evaluated. It is often difficult to separate the effects of medication use from the underlying severity of inflammation that makes medication use necessary or indicated, a concept termed *confounding by indication*.¹⁷⁴ This association has been highlighted further by widespread use of tumor necrosis factor (TNF) inhibitors for patients with refractory disease and the potential for these medications to interfere with innate immune tumor surveillance.

In 1978, an SIR of 2.7 for lymphoma was reported in a group of 46,101 Finnish RA patients compared with the general population.¹⁷⁵ A similarly increased risk of 2.4 for lymphoma was seen later in a group of 20,699 Danish patients,¹⁷⁶ and an SIR of 1.9 to 2 was reported in a large cohort of 76,527 Swedish patients.^{177,178} In the United States, an increased risk of 1.9 was found in a cohort of 18,527 patients,¹⁷⁹ and an SIR of 2.2 was noted in a separate cohort of 8458 patients 65 years old and older.¹⁸⁰ In the United Kingdom, an SIR of 2 to 2.4 for lymphoma was observed in an inception cohort of 2015 patients with inflammatory arthritis compared with the general population,¹⁸¹ and an SIR of 2.04 to 2.39 was seen for non-Hodgkin's lymphoma in a cohort of 26,623 RA patients in Scotland.¹⁸² A meta-analysis of nine cohort studies of RA patients found a pooled SIR of 3.9 for lymphoma using a random effects model.¹⁶¹ Canadian investigators found an increased risk of leukemia (SIR, 2.47) among RA patients, but were unable to confirm elevated rates of lymphomas compared with the general population.¹⁸³ Data from case-control studies of patients with non-Hodgkin's lymphoma have shown similar results: Odds ratios of 1.3 to 1.5 were found for underlying RA.^{160,162} These associations have been recently confirmed in other populations, including patients from Japan,¹⁸⁴ Taiwan,¹⁸⁵ California,¹⁸⁶ and Spain.¹⁸⁷ In general, lymphomas in patients with RA seem to be predominately diffuse large B cell type and recently have been shown to favor nongerminal center subtypes.¹⁸⁸

Most studies have suggested that the risk for development of lymphoma is related to the degree of inflammation. The Swedish group identified high inflammatory activity (defined by ESR, swollen and tender joint counts, and the physician's global assessment of disease activity) as a significant risk factor, with an odds ratio of 25.8 compared with low disease activity.¹⁸⁹ No association between any specific drug and the development of lymphoma was identified; however, the cohort examined was treated between 1965 and 1983, and few of these patients were apparently treated with immunosuppressive drugs, making the lack of association less certain. In a follow-up case-control study of 378 lymphomas in a Swedish group of RA patients published more recently, a 71-fold increased risk of lymphoma was reported in patients with high cumulative disease activity compared with low disease activity.¹⁹⁰ Immunosuppressive therapy did not seem to modify risk for lymphoma in this study. Patients did not have increased rates of lymphoma development before disease onset.¹⁹¹ Patients with Felty's

syndrome (a variant of RA associated with neutropenia and splenomegaly) were found in a Veterans Affairs study of 906 men to have a twofold increase in total cancer incidence, but a 12-fold increase in risk of non-Hodgkin's lymphoma.¹⁹²

Disease-Modifying Antirheumatic Drug Therapy

Several studies have looked at the contribution of disease-modifying antirheumatic drug (DMARD) therapy to the elevated risk of malignancy in RA patients. A prospective, observational study was performed in a group of Canadian RA patients enrolled in a DMARD registry.¹⁹³ Although this study found an increased rate of lymphoproliferative disorders in this cohort compared with the general Canadian population (SIR, 8.05), no significant differences in DMARD exposure were noted between patients who developed malignancy and patients who did not. A second group of Canadian investigators similarly identified an increased risk for the development of lymphoma and myeloma in RA patients overall compared with control groups.¹⁹⁴ In this study, the risk of lymphoma and myeloma seemed to be fourfold greater in the RA group when DMARD use was not controlled for and 3.4-fold greater when individual DMARD use was controlled for. Despite the low level of DMARD exposure in this population, no strong effect of DMARD use was seen.

Similar effects of DMARD use were seen in the study of Swedish patients with RA and lymphoma: Treatment with any DMARD (odds ratio [OR], 0.9) or specific use of methotrexate (OR, 0.8) did not seem to be associated with increased risk of lymphoma compared with DMARD-naïve RA patients; however, no patients had been treated with TNF inhibition.¹⁷⁷ In contrast, a European cohort of RA patients enrolled in a DMARD registry was evaluated longitudinally for the development of malignancies.¹⁹⁵ Investigators found an increased risk of lymphoproliferative disorders in patients with the highest cumulative exposure to DMARDs compared with patients with less than 1 year of exposure (SIR, 4.82).

Although inconclusive, data from these studies when taken together suggest a possible increased risk for the development of lymphoproliferative disorders in RA patients treated with DMARDs. More recent studies have suggested, however, that this increased risk may be due to the duration and severity of the underlying disorder, rather than to specific medication use. Associations of specific immunosuppressive therapy for the treatment of autoimmune diseases are discussed further in Chapters 61 and 62.

Risk of Solid Tumor in Patients with Rheumatoid Arthritis

Despite persuasive evidence of increased risks of lymphoproliferative disorders associated with underlying RA, overall rates of all-site malignancies do not seem to be higher compared with the general population.^{175-177,182,183,196,197} The overall "null" result of all malignancies is due to the combination of increased risk of lymphoproliferative disorders offset by an apparently decreased risk of colorectal malignancies.^{175-177,182,183,198} The decreased risk of colorectal

cancer has been attributed to long-term use of NSAIDs among RA patients. Aside from lymphoproliferative disorders, only a few solid tumors, including lung cancer and skin cancer, have been associated with RA.

Increased risk of lung cancer in RA patients has been seen in multiple studies.^{175-177,182-187,196-198} A study evaluating three separate RA cohorts (an inpatient registry of 53,067 prevalent cases of RA, an inception cohort of 3703 incident RA cases, and a registry of 4160 RA patients treated with TNF inhibitors) found a consistently increased risk of lung cancer in all cohorts (SIR, 1.48 to 2.4) compared with the general population.^{81,198} This association may be related to tobacco use, which seems to be a common risk factor for the development of RA, in addition to its well-known association with lung cancer,¹⁹⁹ although the particular association of lung cancer among RA patients who smoke is unknown. Similarly, a study of lung cancer in a cohort of 8768 U.S. veterans (92% male) with RA found an increased risk of lung cancer (OR, 1.43; 95% confidence interval [CI], 1.23 to 1.65) after adjustment for covariates such as age, gender, and tobacco exposure.²⁰⁰

A slightly increased risk for the development of non-melanoma skin cancer (most commonly basal cell carcinoma and squamous cell carcinoma) has been noted in several studies,^{175,176,198,201,202} although the significance of these tumors, which carry a low probability of metastasis, is unclear. Unfortunately, nonmelanoma skin cancer is rarely captured in national cancer registries, so its incidence among the general population or subpopulations such as RA is difficult to quantify or compare. Furthermore, important risk factors for nonmelanoma skin cancer, including ultraviolet light exposure, are almost impossible to quantitate in observational studies. What is of greater concern, however, are newer data suggesting an increased rate of melanoma among patients with RA.^{180,185,202-204} Because of the suggestion of increased risk of skin cancer, whether attributed to underlying disease or immunosuppressive therapies, it is reasonable to suggest periodic skin examinations in RA patients, particularly those with other risk factors, including smoking and increased ultraviolet light exposure. Certainly, all suspicious lesions should be evaluated by a dermatologist and biopsy strongly considered.

Systemic Lupus Erythematosus

The risks of developing malignancy in association with SLE have been difficult to estimate in the past. Small series and cohort studies have noted that patients with SLE might be at increased risk for malignancy, including non-Hodgkin's lymphoma, sarcoma, and breast carcinoma.²⁰⁵⁻²⁰⁹ Other small series have not found differences,²¹⁰ however, or have found infrequent associations²¹¹ in number or type of malignancy between patients with lupus and the general population.²¹⁰ Conflicting results also are seen in case-control studies of larger groups of patients, with some cohorts showing an increased overall risk of malignancy,²¹²⁻²¹⁴ although others have failed to do so.²¹⁵⁻²¹⁸ Some studies that did not find increased risk of overall malignancies in patients with SLE have shown increased risk of lymphoproliferative disorders, however.^{160,162,216-218} Confounding factors complicating interpretation of these studies include possible incomplete ascertainment of malignancies, inclusion of

nonrepresentative cohorts of patients with SLE, and selection of inappropriate control populations.²¹⁹

To determine more adequately whether individuals with SLE are at increased risk, studies of large multinational cohorts, systematic reviews, and meta-analyses of pooled data are necessary. The SIR of individual studies has ranged from 1.1 to 2.6.²²⁰ A meta-analysis of six of the clinical cohort studies found a slightly increased risk of overall malignancies in cohorts of patients with SLE, with an SIR of 1.58.²²¹ This analysis showed an increased risk of lymphoma in these cohorts, with an SIR of 3.57 for non-Hodgkin's lymphoma and 2.35 for Hodgkin's disease. A separately performed meta-analysis of the incidence of lymphoma in patients with SLE found an SIR of 7.4.¹⁶¹ Individual hospital discharge database studies have shown a consistently higher risk of non-Hodgkin's lymphoma (SIR, 3.72 to 6.7), but these studies examined only hospitalized patients with SLE.²⁰⁰ Pooled analysis showed a slightly elevated risk for the development of breast cancer, with an SIR of 1.53, but they did not find an increased risk of lung or colorectal cancer in these patients.²²¹ The same confounding factors influencing individual studies are a factor in interpreting these pooled data.

A more recent series of studies analyzing nearly 9500 lupus patients ($\approx 77,000$ patient-years of observation) in a multinational cohort study has helped to define better potential associations with malignancy.^{222,223} The authors found a slightly increased risk of malignancies overall (SIR, 1.15) with higher risks for the development of hematologic malignancies (SIR, 2.75), particularly non-Hodgkin's lymphoma (SIR, 3.64).²²² Forty-two cases of non-Hodgkin's lymphoma were identified, most of which were of aggressive histologic subtypes.²²⁴ The incidence of lymphoma in this study was evident early in the course of SLE, rather than after many years of chronic disease activity or use of multiple immunosuppressive medications.^{223,225} The elevated risk of non-Hodgkin's lymphoma in this cohort seemed to be independent of race or ethnicity, although white patients seemed to have higher rates of malignancy in general compared with patients of other ethnicities.²²⁶ In a case-control study within the multisite international SLE cohort, age, disease-related damage, and smoking were found to be associated with increased risk of malignancy; use of immunosuppressant medications (particularly lagged 5 years) may contribute to increased risk of hematologic malignancy.²²⁷

Although the exact cause of the association is unknown, several theories have arisen to explain the possible connection between SLE and malignancy, especially B cell lymphoma. Some authors have postulated that certain immunologic defects may predispose patients to SLE and B cell lymphoma, including apoptosis dysfunction, chronic antigenic stimulation, and overexpression of *bcl-2* oncogene.^{220,228} Viruses, EBV in particular, also have been postulated as part of the development of SLE and lymphoma.^{220,228} Studies have not conclusively validated any of these theories to date, however.

The relative prevalence of cervical cancer in SLE patients is difficult to estimate because national cancer registries often do not record malignancies in situ. Cervical cancer remains an important issue for women with SLE, and an increased risk may come about for different reasons,

including (1) reduced clearance of human papillomavirus (HPV), the causal agent in most cases of cervical cancer; (2) increased risks of cervical cancer associated with immunosuppressive medications; and (3) reduced rates of routine Pap smears and other screening procedures in a population of patients with chronic illnesses. In the large multinational study performed more recently, the SIR for invasive cervical cancer was found to be elevated at 1.26, albeit with confidence intervals that cross the null.²²² Other studies have confirmed increased risks of abnormal Pap smears and cervical dysplasia in women with SLE.^{229,230} Different studies have implicated increased prevalence of HPV infection and other sexually transmitted diseases,²³⁰⁻²³³ and immunosuppression²³²⁻²³⁵ may partly explain this association. As with mammography, women with SLE seem less likely to undergo routine Pap testing than women in the general population.^{236,237}

Several studies have identified a link between SLE and the development of lung cancer.²²⁵ Indeed, the largest multinational cohort of SLE subjects found an increased incidence of lung cancer compared with the general population (SIR, 1.37; 95% CI, 1.05 to 1.76).²²² Further analyses of the cases of lung cancer in this cohort revealed a variety of tumor types, including adenocarcinoma, bronchoalveolar carcinoma, squamous cell carcinoma, small cell carcinoma, large cell carcinoma, and carcinoid tumor.²³⁸ Most cases (71%) occurred in smokers, 25% of cases were in men, and few (20%) had previous exposure to immunosuppressive agents.²³⁸ To date, no particular demographic or clinical features have been found to explain this apparently increased risk.

Overall, the presence of SLE seems to carry a small increased risk for the development of cancer, particularly lymphoproliferative disorders such as non-Hodgkin's lymphoma, lung cancer, and cervical cancer. The underlying causes of these associations are unknown, but they do not seem to be exclusively related to the use of immunosuppressive or cytotoxic agents.* Data suggest that lupus patients may be less likely to receive recommended cancer screening.

Systemic Sclerosis

Although data are conflicting, most evidence suggests that individuals with systemic sclerosis seem to have an increased risk of developing malignancy.^{240,241} Estimates of the prevalence of cancer among scleroderma patients range from 3.6% to 10.7%.^{241,242} However, 13% of deaths are reported among patients with systemic sclerosis.²⁴³ The malignancies that have been implicated are often observed in organs affected by inflammation and fibrosis, including the lung, breast, esophagus, and skin. The SIR of malignancy in the scleroderma population is 1.5 to 5.1 compared with that of the general population.²⁴⁴⁻²⁴⁹ An apparent increase has been reported in the observed number of cases of lung cancer that occur in the setting of pulmonary fibrosis, but not in association with tobacco use.^{248,250} A different study evaluating 20 lung cancers among 632 scleroderma patients in Australia found that cigarette smoking, but not underlying pulmonary

fibrosis, was associated with increased risk of lung cancer.²⁵¹ Studies have been mixed regarding increased risk or a temporal relationship between scleroderma and breast cancer.^{241,244,252} Older age at the time of diagnosis of systemic sclerosis seems to be a significant risk factor for the development of cancer.²⁴⁵ Data are mixed regarding associations between systemic sclerosis-specific autoantibodies and the development of cancer: Selected studies support potential associations,^{247,253} whereas others do not.^{248,254} A recent study found a close temporal relationship to cancer (within 1 to 2 years of scleroderma diagnosis) in scleroderma patients with positive antibodies for RNA polymerase I/III.²⁵⁵ Expression of RNA polymerase I and RNA polymerase III was detected in the tumors of affected individuals.²⁵⁵

Although the SIR for all malignancies is 1.5 to 2.4, the incidence ratio for lung cancer can be as high as 7.8, and for non-Hodgkin's lymphoma, 9.6. Cases of non-Hodgkin's lymphoma seem to be more likely to occur within the first year of diagnosis of systemic sclerosis.²⁵³ Elevations in incidence have been found for other specific cancers as well, including nonmelanoma skin cancers (4.2), primary liver cancers (3.3), and hematopoietic cancers (2.3)—all having a higher incidence than is seen in the general population. The greatest risk seems to correspond to areas commonly affected by fibrosis, particularly the lung and skin. Esophageal involvement, common to limited and diffuse systemic sclerosis, is the likely cause for an increased incidence of Barrett's esophagus (12.7%)²⁵⁶ and development of esophageal cancer (SIR, 9.6).²⁵⁷ In contrast to the data previously described, one study found no increase in overall or specific malignancies in patients with systemic sclerosis (SIR, 0.91 overall).²⁵⁴ Localized scleroderma, including morphea or linear scleroderma, does not seem to convey an increased risk of malignancy.²⁵⁸ Several reports have described the development of postirradiation morphea in patients treated for breast cancer.²⁵⁹

PRIMARY TUMORS AND METASTATIC DISEASE

Primary Musculoskeletal Tumors

This section does not provide in-depth knowledge of the primary tumors of the musculoskeletal system. Rather, it provides a reference to the most common primary malignant musculoskeletal tumors and symptoms that may arise in association with them. Primary tumors of bone, including benign and malignant tumors, are discussed in greater detail in Chapter 123.

A primary malignant bone cancer is any neoplasm that develops from the tissues or cells found within bone that has the ability to metastasize. Neoplasms may develop or arise from any of the types of cells present within the bone—osteoblasts, chondrocytes, adipose and fibrous tissue, vascular cells, hematopoietic cells, and neural tissue.²⁶⁰ A neoplasm developing from any of these tissues is called a *sarcoma*, which signifies that it is derived from mesenchymal tissue. The bone sarcomas are named for the predominant differentiated tissue type, such as osteosarcomas, chondrosarcomas, liposarcomas, and angiosarcomas.²⁶⁰

The most common manifestation of these tumors is the development of pain in the area of the lesion, which may

*References 205, 216, 218, 220, 227, 239.

Fibrosarcoma

be accompanied by a sympathetic effusion or stiffness in the surrounding joint. This discomfort does not seem to be activity related and is often worse at night. These tumors can manifest, however, as painless masses or as pathologic fractures. Systemic features, such as fatigue, malaise, weight loss, fevers, and night sweats, are rare with all of these tumors except for Ewing's sarcoma.²⁶⁰ Primary malignant bone tumors are uncommon, particularly compared with other types of cancer. They have their highest incidence in childhood and adolescence and constitute 3.2% of childhood malignancies that occur before age 15 years. The incidence has been reported in this age group as 3 per 100,000 individuals.²⁶¹ These tumors commonly arise out of areas of rapid growth, with the most common site of primary bone sarcomas being the metaphysis near the growth plate.²⁶²

Table 122-4 lists the most common types of primary malignant bone tumors. Osteosarcoma is the most common of the tumors and generally occurs in individuals in the second decade of life or in elderly individuals.²⁶³ Osteosarcoma can occur secondary to radiation therapy delivered as treatment for other malignancies. Paget's disease of bone can rarely (<1% of cases) proceed to malignant transformation.²⁶⁴ Severe pain in the setting of Paget's disease may signal transformation to osteogenic sarcoma. Tumors most frequently affect the femur, humerus, skull, and pelvis and can result in pathologic fractures. Survival is usually less than 1 year. Differentiating malignancy from Paget's disease may require a biopsy.^{265,266}

Chondrosarcoma has been reported as the second most common of the malignant bone tumors. This tumor may occur as a primary tumor or as a malignant transformation in the setting of benign lesions, such as enchondromas or osteochondromas.²⁶⁷ Fibrosarcoma is significantly less common than the previously mentioned tumors and accounts for less than 4% of primary malignant bone tumors.²⁶⁸

As a group, round cell tumors include primary lymphoma of bone, Ewing's sarcoma, and metastatic neuroblastoma. Ewing's sarcoma is a common primary bone tumor of childhood. Giant cell tumors as a group account for 4.5% of bone tumors. They usually arise from the metaphysis or epiphysis of long bones, generally around the knee. Most are benign, but a few are malignant lesions, usually arising out of a previously irradiated benign giant cell tumor.²⁶⁰

In addition to the primary malignancies of bone, a plethora of malignant tumors can arise from mesenchymal connective tissue; these are also known as *sarcomas*.^{268,269} They can result in joint complaints, but more often result in soft tissue complaints. They are very rare. Rhabdomyosarcoma is a malignant tumor arising from muscle tissue. It is the

fourth most common solid tumor in children and is responsible for more than half of all soft tissue sarcomas in children. Rhabdomyosarcoma rarely occurs in adults. It can appear at any site, and the symptoms most often are referable to the site involved. Most commonly, rhabdomyosarcoma affects the orbits, genitourinary tract, limbs, head and neck, and parameningeal areas. It commonly metastasizes to lymph nodes, lungs, and bone.^{262,270}

Metastatic Disease

When bone lesions are identified, primary tumors need to be considered, although most malignant lesions in bone are metastatic. Metastasis rarely affects muscles, joints, or adjacent connective tissue. More commonly, it affects bone. The most common sites of metastasis are the spine and pelvis. It is uncommon to find metastatic lesions distal to the elbow, and, although rare, metastasis to the foot is more common than to the hand.²⁷¹ When distal or acral metastasis is identified, it is often associated with lung cancer.²⁷² Primary tumors generally associated with metastases to bone include tumors in the prostate, thyroid, lung, breast, and kidney.²⁷³ Although most skeletal metastases do not produce pain, one of the most common causes of cancer pain is infiltration of bone. The pain can be intense and stabbing or dull. It is often constant rather than intermittent, is worse at night, and often is worse with weight bearing and movement.²⁷⁴ Rheumatic or arthritic complaints often occur before lesions are easily identified on radiographs. Arthritis associated with metastatic carcinoma is most commonly monoarticular and most commonly affects the knee. Metastases to the hip, ankle, wrist, hand, and foot have been reported, but occur less frequently. Breast and lung carcinomas are present in most patients.²⁷⁵ Metastases to the extremities can simulate gout, osteomyelitis, tenosynovitis, or acro-osteolysis. Joint involvement can be related to direct synovial implantation or involvement of the juxta-articular or subchondral bone.²⁷⁶ Table 122-5 presents the clinical features suggestive of underlying metastases.

Radiographic features of bone tumors can be significant when the duration of disease and the type of malignancy are interpreted. Lesions may be lytic or blastic, and patterns of destruction often reflect the aggressiveness of tumors. Well-circumscribed lesions may be indicative of slower growth, whereas a "moth-eaten" pattern with evidence of cortical destruction typically signifies a more rapid rate of growth. What has been described as a permeative pattern suggests an extremely rapid rate of destruction and is often associated with an extraosseous soft tissue mass.²⁶⁰ Computed tomography, magnetic resonance imaging, and radionuclide imaging can provide significant information for diagnosis, staging, prognosis, and therapy.

Postchemotherapy Rheumatism

Several rheumatic or musculoskeletal manifestations can develop in patients after administration of chemotherapy for the treatment of malignancy. Postchemotherapy rheumatism has been best described in patients treated for breast cancer, but has also been described in other malignancies, including ovarian cancer and non-Hodgkin's lymphoma.²⁷⁷⁻²⁷⁹ The phenomenon has been described as a noninflammatory, self-limited, migratory arthropathy. Typically, symptoms develop several weeks to several months after the completion of chemotherapy and often include myalgia, stiffness, arthralgia, and arthritis involving the small joints of the hands, ankles, and knees.²⁷⁸ It can be mistaken for RA based on its symptoms; however, most patients have little or no evidence of synovial thickening and have no radiographic or serologic evidence to suggest RA. The pathogenesis of this process is unknown; however, it is self-limited, usually lasting less than 1 year, and is best treated in a conservative fashion. Evaluation should be performed to exclude recurrent carcinoma or another inflammatory condition. The medications most frequently implicated in this phenomenon include cyclophosphamide, 5-fluorouracil, methotrexate, and tamoxifen.²⁷⁹⁻²⁸¹

Other immunomodulatory agents also have been linked to the development of musculoskeletal findings. Tamoxifen use has been associated with the development of an acute inflammatory arthritis similar to RA²⁸¹; however, a randomized controlled trial of tamoxifen or placebo in 7145 women at high risk for breast cancer (but without a diagnosis of cancer) did not find an increased prevalence of arthralgia or arthritis symptoms in the tamoxifen arm.²⁸² More recently, aromatase inhibitors have been used widely for hormone receptor-positive breast cancer, with increasing reports of associated arthralgia and arthritis. A retrospective, exploratory analysis of the Arimidex Tamoxifen Alone or in Combination (ATAC) trial evaluated the development of joint symptoms in 5433 women with early breast cancer randomized to receive anastrozole alone or tamoxifen alone.²⁸³ When analysis was limited to women who entered the study without joint symptoms at randomization, 35.2% developed joint symptoms on anastrozole compared with 30.3% on tamoxifen ($P < .0001$). However, intensity of symptoms was not different between groups. A prospective, nonrandomized study evaluated the prevalence of musculoskeletal symptoms in women who switched from anastrozole to letrozole because of articular symptoms.²⁸⁴ Most (61%) were able to continue with letrozole, with 28.5% discontinuing the second aromatase inhibitor owing to severe musculoskeletal symptoms. Therefore, switching of aromatase inhibitors may be a reasonable strategy when an initial agent is intolerable because of arthralgia or arthritis; many women continue to be intolerant to more than one agent.

Biologic agents used for the treatment of chronic viruses or a variety of malignancies can similarly lead to autoimmune phenomenon. Use of interleukin-2 can result in spondyloarthritis or inflammatory arthritis. Interferon- α administration can result in seropositive nodular RA and myalgia and arthralgia.^{285,286} Use of interferon can also result in autoantibody formation and features suggestive of SLE and autoimmune thyroid disease.²⁸⁶⁻²⁸⁸

LYMPHOPROLIFERATIVE AND MYELOPROLIFERATIVE DISEASES

Leukemia

Leukemia can result in the development of musculoskeletal complaints. Bone pain, the most common musculoskeletal manifestation, has been reported to occur in 50% of adults with leukemia.²⁸⁹ Long bone pain is more common in children, whereas axial pain is more common in adults. Generally, bone pain is more common in the lower than the upper extremities.²⁹⁰ Overt synovitis can develop in association with acute and chronic leukemia and can lead to the development of monoarticular or polyarticular arthritis.²⁹¹ The pathogenesis seems to be leukemic infiltration of the synovium and subperiosteal tissue. Bleeding or hemorrhage in the joint also may be associated with the process. Most cases of arthritis associated with leukemia are seen in children—14% to 50% compared with 4% to 16.5% in adults.²⁹²⁻²⁹⁴

In a series of adult patients with acute leukemia studied over a 10-year period, 5.8% (8 of 139) of patients presented with rheumatic manifestations. On average, symptoms of arthritis preceded the diagnosis of leukemia by 3.25 months.²⁹⁵ The most common patterns of presentation included asymmetric large joint involvement in association with low back pain, followed by symmetric polyarthritis mimicking early RA. Rheumatic manifestations included morning stiffness, low back pain, nonarticular bone pain, pain out of proportion to objective findings, low-grade fever, and elevation of the ESR. The response to NSAIDs, glucocorticoids, and conventional antirheumatic therapy was reportedly poor, but tumor-directed chemotherapy resulted in substantial improvement of rheumatic manifestations. Patients with these manifestations were more likely to exhibit early osteopenia or lytic bone lesions. Ultimately, prognosis and mortality rates were no different between patients presenting with or without rheumatic manifestations.²⁹⁵

In contrast, a large retrospective study of children with leukemia found that 21.4% (36 of 168) with acute lymphoblastic leukemia and 10.5% (6 of 57) with acute nonlymphoblastic leukemia developed symptoms associated with bones and joints. Thirteen of these patients with acute lymphoblastic leukemia had evidence of bony lesions on radiographs.²⁹⁶ Many of these children had been incorrectly treated for juvenile RA or osteomyelitis before the diagnosis of leukemia. The group with bone lesions seemed to do very well; their condition might fall into a subgroup of childhood leukemia that has a better prognosis.^{291,296} A more recent study found that the presence of subtle blood count changes and nighttime pain may help distinguish leukemia from juvenile RA.²⁹⁴

Multiple Myeloma

Multiple myeloma is a neoplastic proliferation of plasma cells, causing a nonosseous malignant tumor to arise in the marrow. In contrast to the other primary tumors of bone, which have their highest incidence in children and adolescents, myeloma is a tumor of adults, occurring most

commonly in the fifth and sixth decades of life. The most common musculoskeletal feature of this disease is the development of bone pain. Other hallmark features are diffuse pain and stiffness. Patients characteristically develop osteopenia, and osteolytic lesions are seen on radiographs. Lytic lesions, which can occur in any area of the skeleton, are produced by focal accumulations of plasma cells. Osteosclerotic lesions also have been reported.²⁹⁷ True arthritis is rare, but cases of arthritis secondary to articular and periarticular invasion with malignant cells have been reported in multiple myeloma and in Waldenström's macroglobulinemia.²⁹⁸ A secondary feature of the disease, which can often lead to additional musculoskeletal complaints, is the development of hyperuricemia and secondary gout. Sjögren's syndrome and other autoimmune phenomena have also been described in association with multiple myeloma.²⁹⁹

Lymphoma

Musculoskeletal symptoms have been reported in 25% of cases of non-Hodgkin's lymphoma.³⁰⁰ The most common musculoskeletal problem associated with lymphoma is the development of bone pain associated with metastasis or lymphoma in the bone. By report, more than 50% of patients have evidence of bone lesions at autopsy; however, few patients actually present with arthritis or bone pain.^{291,301} Nonetheless, non-Hodgkin's lymphoma has been reported to manifest as a seronegative arthritis with or without other features, such as lymphadenopathy and hepatomegaly, typically seen with this disease. Monarticular and polyarticular involvement can occur. Cases of polyarthritis simulating RA in the setting of non-Hodgkin's lymphoma have been reported.³⁰² Although it is unusual to see direct involvement of the synovium, this has also been reported. Cases with radiographic evidence of bone destruction have been associated with non-Hodgkin's lymphomatous arthropathy.³⁰³ Suspicion of lymphoma should be heightened in patients in whom severe constitutional symptoms seem out of proportion to the degree of arthritis, especially in patients who are negative for rheumatoid factor.

Angioimmunoblastic Lymphadenopathy

Angioimmunoblastic lymphadenopathy is a rare lymphoproliferative disorder marked by the clinical features of lymphadenopathy, hepatosplenomegaly, rash, and hypergammaglobulinemia. Patients can develop a nonerosive, symmetric, seronegative polyarthritis concurrent with other features, or as an initial complaint of the disease.³⁰⁴⁻³⁰⁶ Similar features have been reported with intravascular lymphoma, with a report of a patient presenting with a symmetric polyarthritis accompanied by fever.³⁰⁷ Table 122-6 lists musculoskeletal complaints reported with hematologic malignancy.

Graft-versus-Host Disease

Graft-versus-host disease is a complication of bone marrow transplantation and a major cause of morbidity and mortality in the transplant population. Numerous musculoskeletal complaints arise in the setting of acute graft-versus-host

Table 122-6 Musculoskeletal Manifestations of Hematologic Malignancy

Malignancy	Pathogenesis
Leukemia	Infiltration of synovium
Lymphoma	Metastases or invasion of bone, rarely joint
Angioblastic lymphadenopathy	Vasculitis, cryoglobulinemia
Multiple myeloma	Metastasis or invasion of bone, hyperuricemia

disease (lasting 0 to 3 months) and of chronic graft-versus-host disease (lasting >3 months after transplantation). The most frequent manifestation is involvement of the skin, which in many cases can progress to resemble the changes of systemic sclerosis. Skin changes consistent with eosinophilic fasciitis also have been reported.²⁹⁰ Graft-versus-host disease can lead to symptoms of keratoconjunctivitis sicca and xerostomia resembling Sjögren's syndrome. Other features, including arthralgias, arthritis, myositis, Raynaud's phenomenon, and serositis, have also been reported.²⁹⁰

SUMMARY

A plethora of factors contribute to the development of musculoskeletal syndromes in the setting of autoimmune disease and malignancy. A great many autoimmune disorders are known, and for most, the underlying cause and pathogenesis have not been elucidated. This incredible diversity often makes understanding the relationships between associated symptoms difficult. To allow any generalizations regarding an association between an autoimmune disorder and the subsequent development of malignancy, large numbers of patients must be studied longitudinally for exceptionally long periods. Other confounders complicate the picture. Many of the agents used in the treatment of connective tissue and autoimmune disorders modulate the immune system. These agents may have direct carcinogenic potential, whereas others may affect the immune system in a way that may decrease tumor surveillance, subsequently leading to the development of a neoplasm. Intricately entwined are the unique differences among individual immune systems, not only in healthy individuals, but also in individuals whose immune systems are already altered because of an underlying autoimmune disorder. Although uncommon, it is plausible that virtually any of the autoimmune-based diseases and the agents used to treat them might be associated with malignancy in certain circumstances. Most important, when musculoskeletal symptoms arise, malignancy or paraneoplastic syndromes should be considered in the differential diagnosis, especially when patients present with atypical features of autoimmune disease or are refractory to conventional treatment. In addition, the potential for any agent to induce a neoplastic process must be weighed against its proposed benefits before it can be initiated as therapy.

KEY POINTS

Most mass lesions that involve joints and synovial-lined structures are benign; synovial cysts are the most common. They are not true cysts because they lack an epithelial lining. Synovial cysts may involve joints (Baker's cyst) or tendon sheaths (ganglion cysts). Treatment depends on the symptoms; observation is a reasonable course of action in many cases.

Synovial chondromatosis is an uncommon benign condition characterized by nodules of hyaline cartilage, often ossified, within the subsynovial connective tissue, most frequently involving the knee. Treatment is removal of the nodules.

Tenosynovial giant cell tumor of joints and tendon sheaths, previously known as giant cell tumor of tendon sheath and pigmented villonodular synovitis, affects both sexes equally, usually in the 3rd or 4th decade. Lesions are most often monoarticular, with the knee being involved in 80% of cases. The disease is due to a translocation that results in overexpression of colony-stimulating factor-1. Although they can be locally destructive, the tumors do not metastasize; treatment is removal.

The most common primary malignant tumor of joints is synovial sarcoma, which usually affects children and young adults. The disease has an aggressive course, with a long-term survival of around 50%.

Lymphoproliferative diseases, especially acute leukemia, may involve joints. Joint involvement is most common in children, for whom the reported incidence of joint involvement ranges from 12% to 65%. Arthritis can occur at any time in the course of the disease and can be the presenting complaint. It is due to leukemic infiltration into the synovium.

Joints and periarticular structures are often involved by non-neoplastic, mass-forming lesions, such as synovial cysts and loose bodies. These structures are affected infrequently, however, by benign or malignant neoplasms. Joint neoplasms can be divided into tumors that are primary or arise de novo within the joint and tumors that are secondary and access the joint by invading from neighboring bones and soft tissues, or by spreading from distant sites via the vascular system. Primary joint neoplasms are more common and tend to recapitulate the phenotype of tissues that normally construct the joint and synovial sheath—synovium, fat, blood vessels, fibrous tissue, and cartilage. Regardless of the histologic type, the benign variants greatly outnumber their malignant counterparts, and as a group these tumors tend to develop in the synovium, not in the other periarticular structures. These biologically and morphologically diverse

Tumors and Tumor-like Lesions of Joints and Related Structures

ANDREW E. ROSENBERG

lesions often pose significant challenges in diagnosis and treatment, and their clinicopathologic features are the focus of this chapter.

NON-NEOPLASTIC LESIONS

Synovial and Ganglion Cysts

Cysts are defined as closed compartments or sacs that are lined by epithelium and are frequently filled with fluid. Neither the synovial cyst nor the ganglion cyst is considered a true cyst because each lacks an epithelial lining.

Synovial cysts are common and are formed from the synovial lining of a joint, tendon, or bursa. They are non-neoplastic lesions and are caused by herniation of the synovium through the joint capsule or tendon sheath into neighboring tissues, or by expansion of a pre-existing bursa. In adults, synovial cysts frequently develop in association with a variety of joint disorders, including trauma, osteoarthritis, crystal arthropathies, infection, and rheumatoid arthritis or one of its variants. Most synovial cysts have an anatomic relationship to a joint, and most originate in the posterior aspect of the knee, where they are known as a popliteal or Baker's cyst, followed in frequency by the shoulder and hip. These lesions may also arise in the spine, where they develop from the facet joints, most commonly in the lower lumbar region. The posteromedial region of the knee may be prone to the development of synovial cysts because the synovium-lined joint capsule in this anatomic site may not provide adequate structural support.¹ Synovial cysts of the posterior knee joint are purported to affect 2.4% of children, who, in contrast to adults, are usually asymptomatic and have an otherwise normal knee joint.²

Synovial cysts can enlarge as they become increasingly distended with synovial fluid.¹⁻⁴ Consequently, they may manifest as a periarticular mass, produce progressive joint pain and swelling, limit joint mobility, and compress adjacent neurovascular structures. An example of the last-mentioned item occurs in the spine, where synovial cysts that arise from facet joints may impinge or extend into spinal nerves, causing radicular pain.⁵⁻⁷ Other complications of synovial cysts, which sometimes can produce dramatic clinical findings, are acute rupture and secondary infection.

A variety of radiographic techniques have been used to image synovial cysts. Imaging modalities that provide the greatest quantity of diagnostic information include arthrography, ultrasonography, computed tomography (CT), and magnetic resonance imaging (MRI).¹⁻⁴ All of these modalities reveal synovial cysts to be simple or septated thin-walled structures associated with joints and periarticular

Figure 123-1 Magnetic resonance image shows a high T2 signal intensity, large, oval-shaped synovial cyst that extends from the knee joint into the posterior calf. C, synovial cyst; F, fibula; T, tibia.

structures and filled with fluid, whose density is similar to that of water (Figure 123-1).

Grossly, synovial cysts usually range in size from 1 to 10 cm. Their inner surface is smooth, glistening, and translucent; however, prior hemorrhage or secondary infection may distort this surface by virtue of attached blood clot and inflammatory debris or the generation of granulation tissue. The cyst wall comprises an inner surface lined by flattened or plump cuboidal synoviocytes arranged one or several cell layers thick, which are surrounded by an outer sheath of fibrous tissue (Figure 123-2). Sometimes the synovial lining cells may be hyperplastic and form papillary fronds, and occasionally scattered subsynovial collections of hemosiderin-laden macrophages are indicative of previous hemorrhage. Facet joint cysts often contain abundant amorphous debris surrounded by macrophages and are associated with severe changes of the ligamentum flavum.

Figure 123-2 Wall of a synovial cyst, composed of an inner lining of synoviocytes overlaying a layer of dense, fibrous tissue.

Treatment of synovial cysts varies and depends on their location and associated symptoms. These cysts may be managed successfully with conservative therapy; however, in certain situations, surgical excision is required.¹⁻⁷

Ganglion cysts have been recognized for centuries; Hippocrates described them as being composed of “mucoid flesh.”⁸ They are more common than synovial cysts and arise from tendon sheaths, ligaments, menisci, joint capsules, and bursae.⁸ Occasionally, they develop de novo in the subchondral areas of bone, and rarely, they arise within nerve or skeletal muscle and lack communication with a joint. Intraneural ganglia have been shown to develop from dissection of joint fluid along an articular branch of a nerve.⁹ Ganglion cysts are distinguished from synovial cysts by virtue of the fact that they lack a surface lining of synoviocytes. A variety of hypotheses have been proposed to explain their pathogenesis, but none have been proven.⁸ The most accepted theory is that ganglia develop from mucoid cystic degeneration of periarticular structures. They are commonly associated with repetitive motion activities, inflammatory arthritides, and trauma.

Most ganglia arise along the dorsal and volar aspects of the wrists and fingers and the dorsum of the feet.^{8,10} They usually are asymptomatic and typically manifest as a slowly growing, mobile, firm mass that moves with the structure from which it has arisen (Figure 123-3). Ganglia may be painful if traumatized and can compress adjacent neurovascular structures, producing a variety of symptoms. The radiographic characteristics of ganglia are similar to those of synovial cysts, and they appear on images as small, fluid-filled cystic structures.^{1,10}

Macroscopically, most ganglia are round, but they may form elongate cylindrical structures if they track along a tendon sheath. Ganglia are uniloculated or multiloculated, have thin walls, and are filled with translucent mucoid fluid (Figure 123-4). The cyst lacks an inner cell lining, and the bulk of the wall consists of dense fibrous tissue, which is usually surrounded by areolar tissue (Figure 123-5). In many instances, the cyst wall is distorted by variable quantities of reactive myxoid tissue and muciphages, which result from small ruptures and extravasation of fluid.

When ganglion cysts form, they may remain stable for years or may spontaneously resolve, and ganglia that disappear may subsequently redevelop. Treatment is frequently conservative because of their innocuous nature. Ganglia

Figure 123-3 Round, firm ganglion cyst bulging from the dorsal aspect of the hand.

Figure 123-4 Intact ganglion cyst with thread-like pedicle that attaches to a periarticular structure.

occasionally require aspiration or surgical excision, however, especially if they are symptomatic.

Loose Bodies

Loose bodies and *joint mice* are generic terms for free-floating structures within a joint cavity. They are the most common tumor-like lesions of joints and may be exogenous, such as fragments of a bullet, or endogenous, such as pieces of articular cartilage, osteophytes, menisci, ligaments, or bone.¹¹⁻¹³ When not otherwise specified, the term *loose bodies* refers to detached pieces of articular cartilage or subchondral bone (osteoarticular loose bodies) or both that lie free within the joint, or that have become secondarily embedded in the synovium. Loose bodies can cause pain, crepitation, and locking, and they can limit joint range of motion.

Osteoarticular loose bodies are a secondary complication of a variety of conditions, including trauma, osteochondritis

Figure 123-5 Ganglion cyst wall composed of scattered flattened fibroblasts on the luminal surface and a well-formed layer of fibrous tissue.

Figure 123-6 Large, nodular loose body formed from a semilunar-shaped piece of articular cartilage that is surrounded by newly formed cartilage.

dissecans, and arthritides of various causes. When dislodged, the sloughed articular cartilage remains viable because it receives its nourishment from the synovial fluid, but the bone dies because it derives its nutrition solely from blood vessels. Over time, as the loose body tumbles within the joint, its edges become rounded and smooth; however, it eventually becomes embedded within the synovium. When the synovium encompasses the loose body, it may digest and resorb it, or adjacent subsynovial connective tissue cells may undergo a proliferative and metaplastic response.

These cells produce layers of newly formed fibrocartilage and hyaline cartilage, which may undergo endochondral ossification and are deposited on the surface of the loose body (Figure 123-6). These layers of newly formed tissue surround the centrally located loose body, similar to the cambium layers of a tree, and provide a mechanism for the whole structure to increase gradually in size and become significantly larger than the initial osteochondral defect from which they originated (Figures 123-7 and 123-8). As the loose body enlarges, the innermost portion of original articular cartilage cannot be supported adequately by diffusion of synovial fluid, and it dies and calcifies. This combination of events causes the loose body to appear on x-rays as dense speckled and ring-like calcifications (Figure 123-9). Radiographically and histologically, the differential

Figure 123-7 Loose body with visible layers of newly formed tissue.

Figure 123-8 Loose body composed of sloughed articular hyaline cartilage (bottom) covered by consecutive layers of newly formed metaplastic hyaline cartilage and bone.

diagnosis includes synovial chondromatosis. Treatment is simple excision, which can be done arthroscopically.^{12,13}

Intra-articular Ossicles

Small bony nodules normally occur in the knees of some rodents¹⁴ and other mammals and may rarely occur in humans.¹⁵⁻¹⁷ In rodents, they are constantly found in the

Figure 123-9 Knee with an osteoarticular loose body in the suprapatellar region (arrow).

Figure 123-10 Intra-articular ossicle embedded in the fibrocartilage of the meniscus.

anterior portions of the joint and frequently in the posterior portions as well. In humans, nodules develop within the substance of the meniscus of the knee joint adjacent to its attachments to the tibia.

The exact origin of such structures is unknown, although they probably are true sesamoid bones, as seen in rodents, or they may represent ossification secondary to local injury. This latter possibility is supported by the fact that previous knee trauma has been noted in numerous reported cases. The main symptom of meniscal ossicles is pain after exertion, such as walking or prolonged standing, with relief when the knee is at rest. Radiographs may reveal an intra-articular calcification that can be confused with a loose body. MRI shows the ossicle to be a corticated marrow-containing structure that has increased signal intensity on T1-weighted images and decreased signal intensity on T2-weighted images.^{15,17} The ossicle is located within the lateral or the medial meniscus and appears as a small (≈ 1 cm in diameter), palpable bony nodule (Figure 123-10).¹⁶ If the ossicle is symptomatic, it should be excised; however, if it is an incidental finding, it can be managed conservatively.^{15,17}

NEOPLASMS

Fatty Lesions of the Synovium

Although the subsynovial connective tissue of diarthrodial joints is rich in fat, a true lipoma of the synovium is rare. When these rare tumors develop, they most frequently affect the knee joint and the synovial sheaths of tendons of the hands, ankles, and feet, where they are more common in the extensor than in the flexor synovial sheaths.^{18,19} Synovial lipomas can be sessile or pedunculated, and when pedunculated, they may produce pain if they twist on their stalks and become secondarily ischemic. Synovial lipoma, similar to its subcutaneous counterpart, comprises lobules of mature white adipocytes that are delineated by a thin fibrous capsule.

A more common but still unusual fatty lesion of the joint is lipoma arborescens, also known as *villous lipomatous proliferation* and *lipomatosis of the synovium*.^{20,21} This disorder is

Figure 123-11 Lipoma arborescens manifesting as a suprapatellar mass.

characterized by a diffuse increase in the quantity of subsynovial fat, which bulges into the overlying synovial lining, producing a villous architecture. It is uncertain whether the proliferating fat is neoplastic (lipomatosis) or is a manifestation of a hyperplastic or reactive process. Affected patients are usually adults, but sometimes adolescents and rarely children develop the lesion.²² Lipoma arborescens causes chronic effusions, pain, and swelling, and restricts joint motion.²¹ The duration of symptoms is often long, and symptoms have been reported to be present for as long as 30 years; however, acute onset has been documented.

Lipoma arborescens most commonly arises in the knee (Figure 123-11), especially the suprapatellar portion,

Figure 123-12 Magnetic resonance image of lipoma arborescens shows villonodular mass in the knee joint.

Figure 123-13 Lipoma arborescens composed of a villonodular mass of fatty tissue covered by glistening synovium.

although it also has been observed in the hip, ankle, and wrist joints. It is typically localized to one joint, but several cases of bilateral knee involvement have been described.²¹ Laboratory studies are unremarkable, and the joint fluid is clear and yellow.²¹ Plain films show joint fullness, and findings of osteoarthritis are often present. Arthrography reveals multiple lobulated filling defects, which on CT represent a villonodular mass of low signal intensity that on MRI has the density of fat (Figure 123-12).²³ At surgery, the affected synovium has a prominent villous or villonodular architecture and is tan-yellow (Figure 123-13). Histologically, the lesion comprises sheets of mature adipocytes admixed with nutrient blood vessels, all of which are partially compartmentalized by fibrous septa, and is covered on its intra-articular surface by several layers of synovial cells (Figure 123-14). Synovectomy may relieve the symptoms and prevent effusions, but associated osteoarthritis may be progressive.²¹

Figure 123-14 Lipoma arborescens with subsynovial compartment filled with mature adipocytes and covered by synovial cells.

The clinicopathologic differential diagnosis includes diffuse tenosynovial giant cell tumor, synovial chondromatosis, and synovial hemangioma. These lesions can be distinguished easily from lipoma arborescens by their distinct histologic features. Another disorder that should be included in the differential diagnosis is Hoffa's disease—a condition of irritation, inflammation, and hyperplasia of the synovial lining in regions where fat is normally present, such as adjacent to the patella or patellar ligament.²⁴

Vascular Lesions of the Synovium

Benign vascular tumors of the synovium are rare. Their growth pattern can be localized or diffuse. They tend to predominate in adolescence and young adulthood, but symptoms frequently can be traced back to childhood.²⁵ The joint most commonly involved is the knee, but hemangiomas also have been described in the elbow, the ankle, the tarsometatarsal and temporomandibular joints, and the tendon sheaths of the wrist and ankle.^{26,27} Unusual complications of synovial hemangiomas include a secondary destructive arthritis and Kasabach-Merritt syndrome.

Synovial hemangiomas produce a variety of symptoms, including unilateral, intermittent joint pain and enlargement, which may result in limitation of motion, locking, buckling, and hemarthrosis, especially after minimal trauma.²⁶ Classically, the affected joint diminishes in size if sufficiently elevated to allow the blood to drain out of the lesion. On physical examination, the joint is swollen and doughy, and nearby cutaneous hemangiomas may be evident. Joint aspiration frequently yields bloody fluid. Preoperative diagnosis of localized hemangioma is difficult, and the differential diagnosis includes localized tenosynovial giant cell tumor, and in the knee includes discoid meniscus, meniscal tears, cysts, and ossicles.²¹ The diffuse hemangioma is more easily identified, but it can mimic diffuse tenosynovial giant cell tumor and hemophilic arthropathy.

Radiographic evaluation may show nothing more than a vague soft tissue shadow indicative of a swollen synovium and a distended joint capsule or regional osteoporosis in patients who have had long-term symptoms and recurrent hemarthrosis. Rarely, calcified phleboliths are apparent; however, they are associated more often with a soft tissue arteriovenous malformation with secondary joint involvement than with an isolated intra-articular hemangioma (Figure 123-15). Arthrography may show an intra-articular filling defect, and arteriography may be negative in small localized capillary hemangiomas, but contrast material may collect in the more diffuse lesions that contain cavernous or large ectatic vascular spaces (Figure 123-16). CT reveals a lobulated soft tissue mass with mild enhancement after contrast injection.²¹ MRI may show the tumor to have a low to isointense signal on T1-weighted images and high signal intensity on T2-weighted images.²⁸

Macroscopically, the localized hemangioma tends to be small, but larger lesions (8 cm) have been documented.²⁸ It may be poorly defined, well circumscribed, sessile, or stalked, and ranges in color from red to dark blue-purple. Microscopically, the hemangioma is usually of the cavernous or venous type, with large dilated blood-filled vessels lined by cytologically benign endothelial cells. In arteriovenous

Figure 123-15 Localized synovial hemangioma with phleboliths prominently seen in the joint (arrows). The patient is 16 years old with painful swelling for many years when standing and relief of this pain when the knee is flexed.

hemangioma, which grows in a diffuse fashion, the entire synovium may be edematous and beefy red or stained brown by hemosiderin, and consists of prominent tortuous, congested vessels that may penetrate the joint capsule and extend into neighboring soft tissues. Histologically, the vessels recapitulate architecturally abnormal arteries, veins,

Figure 123-16 Arteriogram of an arteriovenous malformation in the soft tissues of the thigh and leg with involvement of the knee joint. The extensive vascular blush in the knee indicates aberrant synovial and capsular vasculature.

and capillaries; have abnormal interconnections; and are arranged in a disorganized tangle.

Therapy for a localized hemangioma is marginal surgical excision, which usually is curative. Diffuse lesions frequently are difficult to eradicate because of their extensive nature. Incomplete excision or debulking may be the only surgical option. Radiation therapy is not indicated.

Fibroma of Tendon Sheath

Fibroma of tendon sheath is an uncommon benign neoplasm that clinically mimics tenosynovial giant cell tumor but is morphologically distinct. Fibroma of tendon sheath first was identified as a clinicopathologic entity in 1936, and since that time, more than several hundred cases have been reported.^{29,30} A translocation $t(2;11)(q31-32;q12)$ that has been identified in this tumor is likely related to its molecular genesis.

Fibroma of tendon sheath usually arises from the tendons and sheaths of the flexor surfaces of the distal extremities; approximately 70% of cases involve the fingers or hand. Of the fingers, the thumb is affected most frequently, followed in descending order by the index and middle fingers.²⁹ Less commonly, large diarthrodial joints such as the knee and rarely the elbow and ankle are sites of origin.^{29,31} Patients range in age from infants to the elderly, but the median age is the early 4th decade of life.^{29,30} Most series report a male predominance, with the largest study of 138 cases having a male-to-female ratio of 3:1.²⁹ Patients present with a slow-growing, painless mass that usually has been noted for several months to a year.³⁰ In 6% to 10% of cases, a history of antecedent trauma is reported. Tumors developing in large joints can be painful, can restrict range of motion, and may be palpable.³²

Plain x-rays show soft tissue fullness; rarely is evidence of bony erosion noted.²⁹ CT or MRI shows a solid, well-circumscribed mass of soft tissue density that usually has low signal intensity on T1-weighted and variable intensity on T2-weighted images. At surgery, the tumors are often attached directly to the tendon or tendon sheath. They are rubbery, oblong, well circumscribed, or encapsulated; average 1.5 to 1.8 cm in greatest dimension; and have a tan-white cut surface (Figure 123-17).^{29,30}

Figure 123-17 Fibroma of tendon sheath that formed a well-circumscribed, tan-white mass.

Figure 123-18 Fibroma of tendon sheath composed of a hypocellular collagenous mass.

Microscopically, fibroma of tendon sheath is multilobular, with clefts interposed between adjacent lobules. The lobules are composed of spindle and stellate fibroblasts enmeshed in a collagenous and sometimes myxoid stroma (Figure 123-18). Immunohistochemically, the tumor cells have the staining profile of myofibroblasts, and ultrastructurally, the cells have features of fibroblasts and myofibroblasts.³³

The natural history of fibroma of tendon sheath consists of slow growth that eventually ceases. The treatment of choice is surgical excision, but a 24% recurrence rate has been reported.²⁹

Synovial Chondromatosis

Synovial chondromatosis is an uncommon condition characterized by the formation of multiple nodules of hyaline cartilage within the subsynovial connective tissue. If the cartilage nodules undergo endochondral ossification, the term *synovial osteochondromatosis* is appropriate. It is unclear whether the proliferating cartilage is metaplastic or neoplastic; however, more recent cytogenetic abnormalities involving chromosome 6 found in the cartilage of these lesions support a neoplastic process.³⁴ Regardless, synovial chondromatosis is benign and does not metastasize.

Synovial chondromatosis most commonly affects middle-aged men, with an average age in the 5th decade of life.³⁵ Middle-aged women are more likely to develop the disease in the temporomandibular joint. The genders are equally affected with regard to hand and foot involvement, and patients with hand and foot involvement are usually in their 6th decade.

Patients commonly describe joint pain, swelling, stiffness, crepitance, and limitation of motion with a locking or grating sensation on movement.³⁵ Symptoms usually are long-standing, recurrent, and progressive.

Synovial chondromatosis typically arises in large diarthrodial joints. The knee is affected in more than 50% of cases, usually as a monoarticular condition.³⁵ Other common sites include the hip, elbow, shoulder, and ankle. Infrequently, synovial chondromatosis arises in the small joints

of the hands and feet and in the temporomandibular joint.³⁶ When cartilage nodules develop in the synovial lining of bursae, tendons, and ligaments, this is known as *extra-articular synovial chondromatosis*.³² The extra-articular variant most commonly affects the fingers, followed by the toes, hand, wrist, foot, and ankle, and more than one synovial sheath may be involved.³²

Plain x-ray findings largely depend on whether the cartilage nodules are calcified or ossified, and whether they erode adjacent bony structures. Visible calcifications are absent in 5% to 33% of cases; however, most often, multiple oval intra-articular radiodensities range in size from a few millimeters to several centimeters (Figure 123-19).³⁷ The pattern of mineralization varies and may appear as irregular flecks that represent calcified cartilage or show a trabecular architecture, which is a manifestation of endochondral ossification. Lesions that are not mineralized can be seen on an arthrogram because they produce multiple filling defects. In approximately 11% of cases, nodules erode the neighboring skeleton, especially along the anterior aspect of the distal femur.

CT may show mass-like nodules in the synovium that have a density similar to skeletal muscle. CT also can detect small calcifications and erosions before they are apparent on plain films. MRI shows that the nodules of cartilage have low signal intensity on T1-weighted sequences and high intensity on T2-weighted sequences; this reflects the high water content of the hyaline cartilage.³⁷ Areas of calcification or mineralized bone have a low signal intensity on T1-weighted and T2-weighted sequences. CT and MRI scans are helpful in identifying the intra-articular source of the lesion and its anatomic extent. In long-standing disease, the bones adjacent to involved joints may be osteoporotic and may show changes of secondary osteoarthritis.

Figure 123-19 Synovial chondromatosis of the elbow. Multiple large calcified bodies fill the joint space and are adjacent to bone.

Figure 123-20 Synovial chondromatosis of the hand and forearm. Multiple calcified nodules of varying size are evident in the soft tissues of the fingers, wrist, and forearm.

The cartilage in extra-articular synovial chondromatosis has similar radiographic changes.³⁷ Nodules of cartilage are frequently mineralized and may appear as a linear arrangement of small calcific densities that are aligned along the sheath and that can span many joints (Figure 123-20).

The radiographic differential diagnosis of synovial chondromatosis includes osteochondritis dissecans, osteoarthritis with loose bodies, tuberculosis, hemopathic arthropathies, pseudogout with extensive synovial calcification, and synovial tumors. In many instances, the clinical presentation and the radiographic picture should lead to the correct diagnosis. However, in many cases, x-rays and the clinical picture are vague, so that only a biopsy specimen can remove all doubt about the diagnosis.

Characteristic of synovial chondromatosis is a thickened synovium containing numerous opalescent firm nodules of cartilage that bulge from the surface in a cobblestone pattern (Figure 123-21). These nodules usually measure less than 5 cm and may lose their attachment to the synovium and form loose bodies, sometimes hundreds of them. The calcified cartilage is white, and areas of ossification manifest as gritty tan trabeculae, which may house fatty marrow. The synovium adjacent to the cartilage may show reactive changes, such as edema, hyperemia, hyperplasia, and villous transformation.

Figure 123-21 Intraoperative appearance of synovial chondromatosis. Innumerable nodules of cartilage fill the joint.

Figure 123-22 Synovial chondromatosis with nodules of hyaline cartilage in the synovium.

Figure 123-24 The cartilage in synovial chondromatosis can be cellular, and the chondrocytes may exhibit limited cytologic atypia.

Cartilage develops in the connective tissue of the subsynovial compartment (Figure 123-22). Neoplastic chondrocytes produce the hyaline matrix that eventually forms individual nodules, which peripherally abut surrounding tissues (Figure 123-23). Cartilage varies in its cellularity, and chondrocytes range from small to large; some may be binucleate and hyperchromatic, similar to the chondrocytes in intraosseous chondrosarcoma (Figure 123-24). Despite these histologic findings of concern, experience has shown that hypercellular variants with atypical chondrocytes usually behave in a benign fashion. Infrequently, the disease manifests as a single, solitary nodule of cartilage, which may be very large and may undergo partial endochondral ossification. Intra-articular osteochondroma can severely limit joint motion and may be confused clinically with other types of neoplasms.³⁸

Over time, nodules of cartilage attached to the synovium are invaded by blood vessels. This invasion results in endochondral ossification, with woven and lamellar bone formation and the development of a medullary cavity with fatty

marrow (Figure 123-25). If these nodules lose their synovial attachments and become free-floating, they may continue to increase in size, because the cartilage derives its nourishment from synovial fluid, although the osseous portion and the marrow die.

The treatment of choice for synovial chondromatosis consists of excision of the involved synovium and removal of all loose bodies. The prognosis is good, although recurrences may be noted if removal is incomplete. Most recurrences develop in the setting of diffuse involvement of the synovium.

Synovial chondromatosis rarely undergoes malignant transformation into chondrosarcoma, although in one series, this phenomenon occurred in 5% of cases. However, a significant percentage of the few reported cases of synovial chondrosarcomas have shown evidence of underlying synovial chondromatosis.^{39,41} The chondrosarcomatous component exhibits dense hypercellularity, marked cytologic atypia, and mitotic activity; the stroma is often myxoid.

Figure 123-23 Nodules of hyaline cartilage merging with surrounding connective tissue in synovial chondromatosis.

Figure 123-25 Nodules of cartilage in synovial chondromatosis undergoing endochondral ossification.

Chondroma of Tendon Sheath and Periarticular Structures

A solitary soft tissue chondroma is considered to be a benign neoplasm. It commonly arises in tendon sheaths and infrequently involves joint capsules or other periarticular structures.

Tendon sheath chondromas usually arise in the flexor tendon sheaths of the distal extremities and are about three times more common in the hands than in the feet.⁴²⁻⁴⁴ They affect the sexes equally and are detected in early to mid-adulthood, presenting as a painless, slowly growing, firm mass. Radiographically, tendon sheath chondromas appear as an extraosseous, well-delineated soft tissue mass that contains calcifications, which are punctate or ring-like in 33% to 70% of cases.^{45,46} Grossly, the tumors are ovoid, firm, blue-white, well-circumscribed masses of hyaline cartilage that are usually 1 to 2 cm in dimension and, in contrast to synovial chondromatosis, are solitary. Histologically, the hyaline cartilage is well formed with occasional small foci of myxoid change. The cartilage can be cellular, and chondrocytes may show limited cytologic atypia; this sometimes causes confusion with chondrosarcoma.⁴⁷ The treatment of choice is simple excision, which is infrequently associated with local recurrence.^{43,44,47}

The intracapsular and periarticular regions are uncommon sites for soft tissue chondromas. When they occur, they usually originate in the anterior infrapatellar region of the knee (Figure 123-26).⁴⁸ In this location, chondromas can achieve a large size (8 cm) and may interfere with knee motion. Their morphology and biologic behavior are similar to those of soft tissue chondromas that arise elsewhere. Intracapsular chondromas have been reported in the knees of three members of a family with familial dysplasia epiphysealis hemimelica.⁴⁵ Two other cases have been described in

Figure 123-26 Intra-articular solitary chondroma of the knee in the infrapatellar region; it is a well-delineated mass with amorphous dense calcification, suggesting mineralized cartilage. (Courtesy Dr. C. Campbell.)

which cartilaginous hamartomas of the volar plates of the proximal and distal interphalangeal joints of the hands and feet were associated with peculiar hypertrophic skin lesions of the hand and hemihypertrophy of the limb.

Tenosynovial Giant Cell Tumor

Tenosynovial giant cell tumor comprises a group of benign tumors that affect the synovial lining of joints, tendon sheaths, and bursae.⁴⁶ These lesions were previously known as *giant cell tumor of tendon sheath*, *localized nodular synovitis*, and *pigmented villonodular synovitis*. Tenosynovial giant cell tumor may be localized or diffuse and may be locally aggressive in that it may invade into bone, grow through joint capsules, extend along tendons, and infiltrate into adjacent soft tissues. Despite its destructive potential, this lesion does not have the capacity to metastasize.

The common histologic denominator of these lesions is the neoplastic proliferation of synovial-like cells that may form a localized mass or spread along the synovial surface and invade downward into subsynovial connective tissue. The growing cells expand the subsynovial compartment, producing finger-like extensions, villi, and redundant folds. These projections often fuse into nodules and form convoluted lobulated masses admixed with a tangle of hair-like villi. The process may be a local phenomenon involving only part of the synovial lining, or it may be extensive, with the whole synovial surface affected.

Until recently, the origin of tenosynovial giant cell tumor was unknown. Previously considered a reactive process, possibly in response to repeated hemorrhage, many tenosynovial giant cell tumors now have been shown to result from a translocation between chromosomes 1p13 and 2q35 in which the gene encoding colony-stimulating factor-1 is fused to the collagen VI alpha-3 (COL6A3) gene.^{46,49,50} Consequently, overexpression of colony-stimulating factor-1 occurs in the neoplastic cells, which account for only 2% to 16% of cells in the mass.⁴⁹ The remaining cells largely represent non-neoplastic inflammatory cells that are recruited into the tumor because they contain the receptor for colony-stimulating factor.^{49,51} This phenomenon has been termed a *landscape effect* and is also observed in certain types of lymphomas and sarcomas.

Tenosynovial Giant Cell Tumor of Joints and Tendon Sheaths: Diffuse Type (Synonym: Pigmented Villonodular Synovitis)

The diffuse type of tenosynovial giant cell tumor of the joint involves large areas of the synovial lining, although uninvolved areas are invariably present. Its incidence is approximately 1.8 per 1 million. Although it may occur in all age groups, spanning children to the elderly, most affect young adults are in the 3rd to 4th decade of life.⁵² The sexes tend to be equally affected, although some series have reported a predominance of males or of females.⁵²⁻⁵⁴

Diffuse tenosynovial giant cell tumor of the joint usually manifests as monoarticular arthritis. Bilaterality or involvement of multiple separate sites has been infrequently reported. Some patients with polyarticular disease also have had significant congenital anomalies. Primary complaints include pain and mild intermittent or repeated bouts of

swelling. Symptoms develop insidiously and progress slowly over a long time, ranging from months to years.^{52,54} The involved area may be stiff, swollen, and warm, and a palpable mass sometimes can be appreciated. Point tenderness can be detected in approximately 50% of patients. Anatomic instability of the involved joint is uncommon.

The knee joint is affected most commonly and is involved in about 80% of cases.^{52,54} The next most frequent sites are the hip, ankle, calcaneocuboid joints, elbow, and tendon sheaths of fingers and sometimes toes. Occasionally, the palm, the sole of the foot, and unusual locations such as the temporomandibular joint and posterior elements of the spine are involved. Bursal involvement is rare, but if it happens, it usually occurs in the popliteal and iliopsoas bursae and the bursa anserina. Infrequently, the disease affects large tendon sheaths proximal to the ankle and wrist, and produces a periarticular soft tissue mass.^{55,56} It is thought that some of these lesions dissect through a joint capsule or a tendon sheath and extend along fascial planes to produce a soft tissue mass.⁵⁵

Invasion of bone on either side of a joint can be seen with intra-articular, bursal, or tendon sheath involvement. This most frequently occurs when the tumor involves "tight" joints, such as the hip, elbow, wrist, and feet, or when tendon sheaths are closely apposed to neighboring bones (Figure 123-27).^{57,58} Rarely, only one bone may be invaded by an intra-articular lesion, and in this situation, it may be difficult to distinguish this type of lesion from a primary bone tumor (Figure 123-28).⁵⁹

Joint aspiration frequently yields blood-tinged brown fluid that lacks diagnostic abnormalities.⁶⁰ Synovial fluid analysis may show a low glucose content, a minimally elevated protein level, and a fair mucin clot. The inflammatory cell count is usually low but may be elevated. Similar findings can be seen in trauma, Charcot's joint, bleeding disorders, sickle cell disease, and Ehlers-Danlos syndrome.

Figure 123-27 Pigmented villonodular synovitis involving the small joints of the foot with multiple bone erosions. No calcification is present in the lesion.

Figure 123-28 Pigmented villonodular synovitis involving the tibio-fibular joint with an adjacent extensive soft tissue mass and eccentric erosion of both bones, simulating a primary bone tumor. The knee joint is normal.

In at least two-thirds of cases, a soft tissue density due to the tumor or effusion or both can be visualized on a plain film.⁶¹⁻⁶⁴ Joint narrowing or calcification is uncommon. Arthrography may show numerous nodular filling defects that extend into an expanded joint space. Arteriograms are unusually striking owing to the prominent vascularity of the tumor. There tends to be an inverse correlation between the degree of vascularity and the amount of fibrosis or scarring of the lesion.

CT and MRI are useful in delineating the extent of disease and can detect intralesional lipid and hemosiderin deposits, which are important diagnostic features.⁶¹⁻⁶³ The tumor has low signal intensity (equal to that of skeletal muscle) on T1-weighted images and is heterogeneous on T2-weighted images. Extension into the bone manifests radiographically as multiple, well-margined, subchondral cyst-like lucencies or juxtacortical oval pressure erosions (see Figures 123-27 and 123-28).^{58,59} In the knee, the femoral area adjacent to the intercondylar region is the site most frequently invaded as the tumor grows along the cruciate ligamentous insertions. Periarticular osteopenia, periosteal reactions, and joint destruction are unusual because the joint space is preserved until late in the course of the disease.^{62,63} The radiographic differential diagnosis of a given case includes (1) tuberculosis, which generally involves more osteopenia and joint destruction; (2) hemophilia, which is also associated with more extensive joint destruction; (3) synovial chondromatosis, which frequently has calcified radiopaque bodies; and (4) rheumatoid arthritis, which shows more severe osteopenia and joint narrowing.

Grossly, the synovium in diffuse tenosynovial giant cell tumor is red-brown to mottled orange-yellow and looks like a plush Angora rug (Figure 123-29). Matted masses of villous projections and synovial folds are prominent and are admixed with sessile or pedunculated, rubbery-to-soft

Figure 123-29 Diffuse type of tenosynovial giant cell tumor consisting of mottled brown-yellow-red villonodular mass.

nodules (0.5 to 2 cm in diameter). The synovial membrane is thick and succulent, and is often coated with a fibrinous exudate. Red-brown or golden brown tissue may extend deep into subsynovial structures or may invade the joint capsule. If a tendon sheath is involved, a sausage-shaped mass may be evident because the sheath is distended by the proliferating tumor. If the joint capsule is invaded, adjacent soft tissue structures, including nerves and vessels, may be covered by wispy, red-brown tissue. If soft tissue invasion is extensive, the lesion may appear as a soft-to-rubbery, red-brown mass with foci of hemorrhagic cysts. Similar tissue may be present near the chondro-osseous junction or may be wrapped around vascular and ligamentous attachments to bone surfaces, which represent entrance points into the interior of the bone. Although other conditions, such as hemochromatosis and hemosiderosis, also may discolor the

Figure 123-30 Diffuse type of tenosynovial giant cell tumor growing with a villonodular architecture. Invading cells produce the nodular configuration.

Figure 123-31 Synovial lining cells covering the mass of proliferating polyhedral cells admixed with multinucleated giant cells.

synovium brown, the nodular component is usually absent; in addition, microscopic features are definitive for separating these entities (see later).

Microscopic examination reveals marked synovial cell hyperplasia with surface proliferation and, more important, subsynovial invasion by masses of mitotically active polygonal or round cells with moderate amounts of eosinophilic cytoplasm and round nuclei (Figures 123-30 and 123-31). Included among the invading synovial cells are scattered lymphocytes, multinucleated giant cells (osteoclast, Touton, or foreign body type), hemosiderin-laden macrophages, and fibroblasts. Hemosiderin also can be seen between cells and in synovial lining cells and polygonal cells. Foci of hemorrhage are common and are surrounded peripherally by giant cells and macrophages (Figure 123-32). Scattered collections of foamy macrophages (xanthoma cells) filled with lipid also are a frequent finding. These different cell populations fill and distend the synovial villi, causing them to fuse with adjacent ones, forming nodules. In some nodules, abundant collagen deposition with hyalinization may cause confusion with neoplastic bone. Rarely, the tumor may contain focally calcified cartilaginous matrix.⁶⁵

Figure 123-32 Sheets of macrophages containing abundant hemosiderin.

Immunohistochemical studies have been interpreted to support a synovial cell or fibrohistiocytic phenotype.^{33,64} The tumor cells express clusterin, D2-40, and a minority of large cells stain with antibodies to desmin.⁶⁶ It is important to note that cells that harbor the translocation express colony-stimulating factor-1 (CSF1). Flow cytometric analyses have shown that some of these tumors, especially tumors that have large extra-articular soft tissue components, may be aneuploid and have high proliferative indices.⁵⁶ Although these flow cytometric findings may help predict which cases would be more locally aggressive, examples of diffuse tenosynovial cell tumors with these attributes have not metastasized.⁵⁶

Treatment of diffuse tenosynovial giant cell tumor of the joint is not standardized and has included radiation therapy, total synovectomy, arthrodesis, bone grafting, and primary arthroplasty. Although no single therapy has been consistently successful, wide synovectomy is currently the recommended treatment.^{52,54} It is difficult to perform an actual complete synovectomy, however; residual involved synovium frequently remains, causing a local recurrence rate of 16% to 48%.^{67,68} Tumors arising in the knee have a higher rate of recurrence compared with tumors arising in other joints. Rarely, recurrent disease or tumors with large extra-articular components may require more radical surgery, such as ray resection or amputation.⁵⁶ Studies have shown that moderate doses of radiation may control and even cure patients with such extensive disease, possibly obviating the need for radical surgery or amputation. Finally, drugs targeting CSF1 are being tested to determine their efficacy in clinically challenging cases.⁶⁹

Malignant Diffuse Tenosynovial Giant Cell Tumor

Malignant tenosynovial giant cell tumor is a rare lesion; only a handful of cases have been reported.⁷⁰⁻⁷³ The knee is the joint that has been most commonly affected, and in many cases, coexisting benign-appearing, diffuse tenosynovial giant cell tumor is noted. In the malignant variant, the neoplastic cells may be spindle or polyhedral shaped and cytologically malignant. These tumors have the capacity to behave aggressively; almost 50% of patients die from metastatic disease.⁷⁰

Localized Tenosynovial Giant Cell Tumor of the Joint (Synonyms: Benign Giant Cell Synovioma, Benign Synovioma, Localized Nodular Synovitis)

Localized tenosynovial giant cell tumor of the joint manifests as a solitary, well-circumscribed mass. It usually consists of a single sessile or pedunculated, sometimes lobulated, tumor that ranges from 1 to 8 cm in diameter (Figure 123-33). Most commonly, it is unilateral, arises in the knee, and is equally distributed between the sexes.⁷⁴

Symptoms are similar to those of diffuse tenosynovial giant cell tumor, except that in the localized variant, a higher frequency of joint locking is reported because the mass interferes with motion.⁷⁴ A few patients may present with acute severe joint pain caused by torsion and infarction of the tumor. Effusions are common, but the synovial fluid tends to be less bloody than in the diffuse variant, and may be clear.

Figure 123-33 Localized tenosynovial giant cell tumor of the joint with attached pedicle. The mass is well circumscribed and brown-yellow.

Imaging studies show a heterogeneous nodular mass that contains lipid and hemosiderin deposits (Figure 123-34). In the knee joint, the tumor frequently arises in the suprapatellar notch, in the femoral notch, and between the meniscus and the joint capsule.⁷⁴ Usually, no bone invasion occurs. Marginal excision is usually curative. Small lesions can be extirpated arthroscopically.⁷⁴

Histologically, localized tenosynovial giant cell tumor of the joint is identical to the nodules of the diffuse variant. The main difference is that the prominent synovial villi present in the diffuse variant are absent or sparse.

Figure 123-34 Magnetic resonance image shows well-delineated dark mass in posterior knee joint.

Localized Tenosynovial Giant Cell Tumor of the Tendon Sheath (Synonyms: Giant Cell Tumor of Tendon Sheath, Fibroxanthoma of Tendon Sheath)

Localized tenosynovial giant cell tumor of the tendon sheath usually involves the hand or wrist, and less frequently the foot or ankle.⁵³ It is the most common soft tissue tumor of the hand and usually arises from the flexor tendon sheaths of the finger; the index finger is affected most frequently, followed in descending order of frequency by the third, fourth, fifth, and first fingers.

Tumors of the digits predominate in females, with a male-to-female ratio of at least 2:1,^{53,75} and tumors of the toes have an equal sex distribution.⁵³ On average, patients are in the 3rd to 5th decades of life and present with a painless, palpable, firm, mobile mass.

Clinically, the mass usually is solitary and is located on the flexor surface, but it may bulge into the extensor or lateral aspects of the digits (Figure 123-35). The tumors are slow growing, and the intervals between detection and surgical treatment have ranged from several weeks to longer than a decade, with an average interval of slightly longer than 2 years.^{53,75}

Radiographically, the tumors appear as well-circumscribed soft tissue masses, and in about 25% of cases, adjacent extrinsic excavation of the cortical bone has a sclerotic margin (Figure 123-36).^{53,75} MRI reveals the lesions to have a hypointense signal on T1-weighted images and either a hypointense or a hyperintense signal on T2-weighted images. These findings are helpful in distinguishing giant cell tumor of tendon sheath from other soft tissue tumors.⁷⁶

The gross pathology is that of a well-circumscribed, multinodular, round, rubbery, variegated red-brown-tan-yellow mass, generally not larger than 5 cm in diameter, which is firmly attached but easily peeled off the involved tendon

Figure 123-35 Tenosynovial giant cell tumor manifesting as a mobile, solid, firm mass.

Figure 123-36 The cortex of the phalanx is eroded by the tenosynovial giant cell tumor.

(Figure 123-37). Sometimes at surgery, the lesion may “pop out” of the incision. The cut surface reveals a solid mass that ranges from hues of yellow to orange-red-brown, depending on the quantity of lipid and blood pigments present. Often bands or septa of white fibrous tissue subcompartmentalize the lesion. The morphology and immunophenotype of the cell types present are identical to those in the diffuse variant (Figure 123-38).^{66,77} Ultrastructurally, proliferating cells have features similar to type A and type B synovial lining cells.⁷⁵⁻⁷⁸ Flow cytometry has been performed on a few cases, and all have been diploid.⁵⁶ Cytogenetics shows that many of these tumors have a translocation between 1p13 and 2q35.^{49,51,79}

These tumors are benign and do not metastasize. Rarely have malignant giant cell tumors of tendon sheath been reported.^{70,80} The treatment of choice is conservative surgical excision, which is usually curative. Local recurrence may be noted if excision is incomplete.^{53,75}

Figure 123-37 Well-delineated, white-yellow and focally brown tenosynovial giant cell tumor.

MALIGNANT TUMORS OF THE JOINT

Malignant tumors of joints are uncommon and are classified into primary and secondary types. Primary malignancies are virtually always sarcomas and usually arise within the synovium of large diarthrodial joints, especially the knee. Patients are adults, who present with chronic symptoms of pain, swelling, and effusion, and most tumors are chondrosarcomas or synovial sarcomas. Rarely, other sarcomas originate within a joint; our experience has included cases of intra-articular myxoinflammatory fibroblastic sarcoma, pleomorphic fibrosarcoma, extraskeletal myxoid chondrosarcoma, conventional chondrosarcoma, malignant tenosynovial giant cell tumor, and angiosarcoma (Figure 123-39). Secondary malignant tumors of joints, by definition, originate beyond the confines of the joint; most are sarcomas that extend from neighboring bone or surrounding soft

Figure 123-39 Angiosarcoma of synovium of the knee joint. The hemorrhagic tumor erodes into the distal femur and proximal tibia.

tissue. Although synovial tissue is highly vascular, metastases or involvement of the synovium by carcinoma, lymphoma, or leukemia is uncommon.

Primary Sarcomas of Joints

Conventional Chondrosarcoma

Conventional chondrosarcoma arising in the synovium is unusual; fewer than 50 cases have been reported in the English language.^{39-41,71,81} In approximately 50% of cases, the chondrosarcoma arose in association with pre-existing synovial chondromatosis.^{40-42,81,82} Patients are usually in the 5th to 7th decade of life and have an equal sex distribution.⁸¹ Typically, patients present with a progressively enlarging mass in the joint that may cause mechanical dysfunction, pain, and stiffness. In patients who have pre-existing synovial chondromatosis, the duration of symptoms is usually long, and in some instances, symptoms may be present for 25 years.⁸¹ Most chondrosarcomas arise in the knee joint, followed by the hip and elbow joints.

Radiographic studies usually show a periarticular soft tissue mass that may have dense irregular or ring-like calcifications. Occasionally, invasion into the medullary cavity of adjacent bone is evident. The radiographic differential diagnosis varies according to the presence of calcification and includes synovial chondromatosis, synovial sarcoma, diffuse tenosynovial giant cell tumor, and chronic synovitis.⁸¹

Grossly, the involved joint is filled with synovium massively thickened by innumerable nodules of opalescent blue-white cartilage. The nodules of cartilage vary in size and may be free-floating in the joint cavity. In several cases, the tumor has extended into adjacent soft tissue and bone.

Microscopically, the tumor is composed of malignant hyaline and myxoid cartilage. Rarely, the matrix is entirely myxoid and has features of extraskeletal myxoid chondrosarcoma.⁸² The neoplastic cartilage is cellular and contains cytologically atypical chondrocytes. The periphery of the lobules of cartilage is typically the most cellular, and in this region, some of the tumor cells are spindled. Other findings include necrosis and permeation of invaded bone.⁸¹ Coexisting synovial chondromatosis can be identified by its well-formed nodules of hyaline cartilage, which are less cellular, containing cytologically banal-appearing chondrocytes and a matrix that is frequently mineralized.

Treatment is usually surgical extirpation with consideration given for chemotherapy in high-grade lesions or lesions that have metastasized. Inadequate surgical removal virtually ensures local recurrence, which may necessitate subsequent radical excision. Metastases have occurred in approximately one-third of reported patients; the lung is the most common site for systemic spread.⁸¹

Synovial Sarcoma

Synovial sarcoma is a common sarcoma that accounts for approximately 6% to 10% of soft tissue sarcomas. It usually develops in the deep soft tissues and rarely arises in joints (Figure 123-40), but it may secondarily invade articular synovium from neighboring soft tissues. Earlier descriptions of this tumor attest to its wide spectrum of morphology

Figure 123-40 **A**, Magnetic resonance image of a rare example of intra-articular synovial sarcoma. The infrapatellar tumor is well circumscribed and has a focal inhomogeneous appearance. **B**, The gross specimen shows that the tan, hemorrhagic tumor bulges into the joint but is covered by synovium.

because such names as *adenosarcoma* and *synovial fibrosarcoma* were used until the term *synovial sarcoma*, first introduced in 1936, became commonplace. The morphology of synovial sarcoma mimics a joint in its early stage of development in that it contains cleft-like spaces and glands delineated by large polygonal (epithelioid) cells surrounded by fascicles of spindle cells. The clefts and glands simulate a microscopic “joint space” that is bounded by synovial lining cells and is supported by subsynovial mesenchymal cells. Because epithelial or spindle cells may predominate, synovial sarcoma has been subtyped into biphasic and monophasic spindle cell and epithelial types, although the latter type is very rare.

Synovial sarcoma commonly affects adolescents and young adults. In a series of 121 cases, the age range was 9 to 74 years, with a median age of 34 years; however, it occurs in children with significant frequency.^{83,84}

The term *synovial sarcoma* implies that the tumor originates from the synovium; however, less than 10% of cases

are intra-articular or show continuity with a synovial lining.^{85,86}

Approximately 60% to 70% of synovial sarcomas arise in the extremities, especially the lower limb, in the vicinity of large joints, particularly the popliteal areas of the knee and foot.^{87,88} Regions of the thigh, hand, leg, and digits may be affected, and in the distal extremities, tumors are often adjacent to joint capsules or tendon sheaths or both. Tumors also have been reported in the neck, torso, craniofacial region, retroperitoneum, orbit, tongue, mediastinum, soft palate, heart, kidney, lung, pleura, and prostate.

No clinical features specific to synovial sarcoma distinguish it from other sarcomas. The most common complaint is the development of a slowly enlarging, deep-seated, palpable mass that is painful in about 50% of cases.^{84,88} Symptoms may be present for an unusually long time, ranging from months to 25 years with an average of about 6 months to 2.5 years, before medical evaluation is sought.^{84,88} Delay in diagnosis is more frequent with tumors that are located in the deep soft tissues than in tumors that are based in the more superficial and clinically noticeable regions. In some cases involving the knee region, vague mild pain over several months may occur before a mass is appreciated, and if the tumor reaches a large size, limitation of motion finally may be noted. Head and neck lesions produce symptoms related to their specific sites, such as hoarseness and breathing or swallowing difficulties. Rarely, a patient may present with a symptom secondary to pulmonary metastasis, such as hemoptysis.⁸⁸

Classically, plain film findings of synovial sarcoma consist of a well-circumscribed, deep-seated soft tissue mass. Synovial sarcoma is one of the few primary soft tissue tumors that frequently calcify. Approximately 30% to 50% of cases reveal radiographically detectable calcifications that may have a fine, stippled, or dense appearance (Figure 123-41).⁸⁹ The calcification may be focal or may present throughout most of the tumor.⁹⁰ Periosteal reaction of adjacent bone is elicited in approximately 20% of cases, but bone is rarely invaded by the tumor.

CT is more sensitive than plain radiography in showing calcification or periosteal reaction. MRI is important in delineating the anatomic extent of the tumor and usually shows a large inhomogeneous mass with areas of hemorrhage. The radiographic differential diagnosis includes hemangioma, lipoma, synovial chondromatosis, soft tissue chondrosarcoma or osteosarcoma, myositis ossificans, aneurysm, and other sarcomas.

The gross pathology of synovial sarcoma reveals a well-demarcated, pink-tan, fleshy mass that easily detaches or “shells out” from its tumor bed (Figure 123-40B). The cut surface is usually uniform, gray-yellow, and rubbery. Calcified areas are gritty and hard. In larger tumors, areas of hemorrhage or necrosis or both with cystification and gelatinous breakdown of tissue may be seen. Synovial sarcoma sometimes grows between tendons, muscles, and fascial planes, or wraps around neurovascular bundles.

Synovial sarcoma is subtyped into three patterns on the basis of predominant microscopic findings: monophasic spindle cell, monophasic epithelial, and biphasic variants. Use of such a classification system requires some subjectivity because many of these tumors have a variable histologic picture. A useful differential observation is that marked

Figure 123-41 **A**, Focally mineralized synovial sarcoma in the deep soft tissues in the vicinity of the elbow joint. **B**, Axial computed tomography scan shows intratumoral calcification.

cellular pleomorphism and atypia usually are not present in synovial sarcoma and, when observed, tend to point to some other type of neoplasm, such as pleomorphic fibrosarcoma.

Microscopically, the hallmark of the more common biphasic synovial sarcoma is the two different populations of neoplastic cells consisting of epithelial and spindle cells (Figure 123-42). Epithelial cells may be cuboidal or columnar and, similar to true epithelium, may have well-defined cytoplasmic borders. These cells may form glandular spaces, line papillae or cleft-like spaces, or grow in cohesive groups (see Figure 123-42). Epithelial cells usually are surrounded by fascicles of uniform small and plump spindle cells. Spindle cell fascicles are densely cellular and frequently are arranged in a “herringbone” pattern. In most biphasic synovial sarcomas, the spindle cell component predominates, and calcification of hyalinized stroma most frequently occurs in spindle cell regions. Some tumors may show bone formation, which may be present in spindle or epithelial areas. In the monophasic variants, spindle or epithelial cells may predominate (Figure 123-43; see Figure 123-42).

Immunohistochemistry has shown that epithelial and the spindle cell components frequently stain with antibodies to keratin and epithelial membrane antigen, which usually are associated with epithelial neoplasms.⁹¹⁻⁹³ This pattern of reactivity has helped make it possible to separate synovial sarcoma from morphologically similar tumors, such as fibrosarcoma and malignant peripheral nerve sheath tumor.⁹³ It has also provided evidence that synovial sarcoma does not arise from or recapitulate the synovium, because normal synovial cells do not stain with these antibodies.⁹⁴

Cytogenetic studies of synovial sarcomas have detected a consistent translocation $t(X;18)(p11.2;q11.2)$ in almost all cases, regardless of whether the tumor is biphasic or monophasic.^{87,95} This finding provides insight into the genesis of synovial sarcoma, which may be related to dysregulation of transcription and can be used as a diagnostic feature. No relationship between the location of the translocation breakpoint and the prognosis has been discerned.

The prognosis of synovial sarcoma is poor. In one study of 150 patients with nonmetastatic disease, 5-year, 10-year,

Figure 123-42 Biphasic synovial sarcoma with epithelial cells forming glands and papillary structures. The spindle cell component surrounds the glands.

Figure 123-43 Monophasic spindle cell variant of synovial sarcoma with the fascicles of tumor cells forming a herringbone pattern.

and 15-year disease-free survival rates were 59%, 52%, and 52%.⁹⁰ Many factors influence prognosis; tumors that are small (<5 cm), that arise in patients younger than 25 years of age, and that lack poorly differentiated areas have a high rate of cure.⁸⁴ In contrast, large tumors (≥5 cm) that arise in patients 25 years old or older and that contain poorly differentiated areas have a dismal outcome.⁸⁴ The impact of histologic subtype has been controversial. Radiographically, the tumors appear as well-circumscribed soft tissue masses. However, in about 25% of cases they produce extrinsic erosion of the adjacent cortical bone, and when this occurs the margin of the excavation is sclerotic (see [Figure 123-36](#)).^{53,75}

The natural history of synovial sarcoma consists of local recurrence, which may be repetitive. Most recurrences manifest within 2 years after initial treatment, but intervals longer than 10 years are not exceptional. Ultimately, metastases occur in many patients, and the most common site is the lungs; regional lymph node involvement has been reported in a few patients.⁹⁶ About 10% of patients die within 1 year after diagnosis with metastatic disease; 90% of these patients have massive pulmonary metastases.

Treatment must contend with issues involved with local and systemic therapy. Successful local control usually can be achieved by limb salvage surgery combined with radiation.^{96,97} Because regional lymph nodes may be involved, their status should be evaluated carefully, and they should be treated if enlarged. Systemic treatment consists of various chemotherapy regimens, which have provided questionable benefit, although adjuvant chemotherapy usually is recommended for patients who are at high risk—patients with tumors larger than 5 cm.⁹⁸⁻¹⁰¹

Secondary Malignant Tumors of the Joint

Sarcomas

Primary sarcomas of bone, such as osteosarcoma and chondrosarcoma, infrequently involve a joint because intact articular cartilage usually acts as a barrier to direct tumor extension. However, when it is observed, joint invasion usually occurs via a pathway created by a transarticular fracture, via growth along tendoligamentous structures, or through capsule insertion sites. This circumstance may make it difficult to distinguish on histologic grounds alone some forms of synovial chondromatosis from a low-grade intraosseous chondrosarcoma that has secondarily spread into the joint.

Similarly, primary soft tissue sarcomas gain access into the interior of a joint by growing through the joint capsule in conduits occupied by pre-existing vascular structures or along tendons and ligaments. This complication can make providing adequate therapy challenging because treatment may require en bloc resection of the joint.

Metastatic Carcinoma

The synovium, in contrast to other richly vascular tissues, is rarely the site of metastatic carcinoma; this may reflect the fact that only clinical cases in which joint symptoms prevail are reported because at autopsy, joints are not routinely examined. Most carcinomas that metastasize to the

synovium originate in the lung, followed by the gastrointestinal tract and breast.⁹⁹⁻¹⁰¹ Affected patients are usually elderly, and the knee is the most frequently involved joint. In many reported cases, the underlying bone also contains metastatic deposits.

Malignant Lymphoproliferative Disease

The various types of malignant lymphoproliferative diseases, including leukemia, lymphoma, and myeloma, can involve the synovium and may produce osteoarticular symptoms.¹⁰²⁻¹⁰⁴ This complication occurs most frequently in leukemia and is seen in both acute and chronic forms.¹⁰⁴ Joint symptoms have been observed in 12% to 65% of children and in 4% to 13% of adults with leukemia.¹⁰⁴ Arthritis can develop at any time during the disease course and can be the presenting complaint. Large joints are affected more commonly than small joints, and the arthritis is often pauciarticular, asymmetric, migratory, and severe. Symptoms may result from leukemic infiltration of the synovium or irritation of the neighboring periosteum. When arthritis is the major presenting symptom, it may cause confusion with septic arthritis, rheumatic fever, subacute bacterial endocarditis, or rheumatoid arthritis.

INDEX

A

- AA amyloidosis, 1894
manifestation, 1889
- Abatacept, 957
administration, 1766
biologic DMARD, 523-524
clinical benefits, 994-995
clinical studies, 989-993
clinical trials, safety assessments, 993
evaluation, double-blind placebo-controlled trials, 989
infections, incidence rate, 994
monotherapy usage, 994
multicenter phase IIb study, 989-990
phase III studies, 990
radiographic benefits, 994-995
role, 994
safety issues, 993-994
usage, 989-995, 1314, 1757
- Abatacept in Inadequate Responders to Methotrexate (AIM)
AIM-2, DNA-sensing cytosolic protein, 144-145
phase III study design, 990f
studies
double-blind phase, 990-991
patient responses, 989t
- Abatacept Study of Safety in Use with Other RA Therapies (ASSURE) trial, 993
findings, 993
- Abatacept Study to Determine the Effectiveness in Preventing the Development of RA in Patients with Undifferentiated Inflammatory Arthritis (ADJUST) study, 992-993
- Abatacept Study to Gauge Remission and Joint Damage Progression in Methotrexate-naïve Patients with Early Erosive RA (AGREE) study, 992
- Abatacept Trial in Treatment of Anti-TNF Inadequate Responders (ATTAIN) phase III study, 991
- Abatacept Trial in Treatment of Anti-TNF Inadequate Responders (ATTAIN) study
clinical responses, 991f
design, 991f
patient responses, 989t
- ABCB1 gene, mutations, 1258
- ABCG2 gene product, 1555-1556
- Abdomen, circumscribed/plaque morphea, 1786f
- Abdominal aortic aneurysms, 675
- Abdominal wound, Koebner phenomenon, 1233f-1234f
- Abductor dysfunction, 694
- Abductor function, physical examination, 694f
- Abetimus sodium (LJP-394), dsDNA strands, 1293
- Abl-kinases, tyrosine kinase activity (inhibition), 1396
- Absenteeism, work disability, 465-466
- A β ₂M amyloidosis, 1894-1895
manifestation, 1889
treatment, difficulty, 1895
- Acetabular joint, arthrocentesis, 782
- Acetabular labrum, impact, 695
- Acetaminophen
adverse effects, 888
glucosamine, comparison, 1652
mechanism, 877
NSAIDs, comparison, 344
paracetamol, pain/fever relief, 877
- Acetylation, 317-318
- Acetylcholine-loaded vesicles, fusion, 63
- Acetyl-coenzyme A (CoA), conversion, 74-75
- Acetylsalicylic acid (ASA)
impact, crystallographic studies, 876
meta-analysis, 882
synthesis, 872
- Achilles tendinitis, 575f
- Achilles tendon (calcaneus tendon), 574-575
area, arthrocentesis, 784
posterior joint pain origin, 701
protection, 701
structural component/kinetic force, 1118
tophi, 1559f
- Achondroplasia (short-limb dwarfism), 1719, 1725
- Acidic NSAIDs, accumulation, 882
- Acid maltase deficiency, 1423-1424
- Acne syndrome, 1612
- Acquired complement deficiency states, 335
result, 335
- Acquired immunodeficiency syndrome (AIDS), T cells (deficiency), 234
- Acquired systemic amyloidosis, 1889
- Acrodermatitis chronica atrophicans (ACA), Lyme disease (association), 611
- Acromegaly, impact, 755
- Acromioclavicular (AC) disorders, 655-656
evaluation, 655
pathophysiology, 655
physical examination, 655
post-traumatic distal clavicle osteolysis, 655
- Acromioclavicular (AC) joint, 639
arthrocentesis, 778
arthrosis, radiographic evaluation, 655
examination, 564
observation, 643
pain, subacromial impingement/rotator cuff pathology (coexistence), 655
tenderness, 643
cause, 643
Zanca view, 644f
- Acromioclavicular (AC) symptoms, 655
- Actin
helical polymers, extension, 72
presence, 246
- Activated B lymphocytes, presence, 1084-1085
- Activated endothelium, vascular injury, 1352-1353
- Activated macrophages, NGF production, 420-421
- Activated memory T cells, promotion, 378-379
- Activated neutrophils, LTB₄ generation, 886-887
- Activating stimuli, effects, 147-148
- Activating transcription factor-6 (ATF6), impact, 387-388
- Activation cascades, 326-329
classical pathway, 326-328
- Activation fragments, detection (tests), 333
- Activation-induced cell death (AICD), 187
phenomenon, 387
- Activation-induced cytidine deaminase (AID), 203-204
expression, 227
- Activator protein-1 (AP-1), 1080, 1094
- Active disease
combination DMARD therapy, 936-937
refractory patients, treatment, 1150-1151
therapies
blind trials, 1141f
clinical trials, 937f
treatment, 1149-1150
- Active DM, cutaneous manifestations, 606
- Active muscle contraction, importance, 88
- Active myositis, 1121
- Active nonrenal SLE (EXPLORER), treatment, 987-988
- Active polyarticular juvenile idiopathic arthritis, plain radiograph, 1767f
- Active scleritis, presence, 621f
- Active suppression, usage, 288
- Activin receptor-like kinases (ALKs), 47-48
- Activities of daily living (ADLs), 1135t
Katz Index, 530
medication adjunct, 1154-1155
modification, 1648
- Activity-related thigh pain, 697f
- Actomysin, cross-bridge cycle, 72f
- Acute active rheumatic valvulitis, mononuclear cellular infiltrates (composition), 1880t
- Acute anterior uveitis (AAU), ERA (association), 1762
- Acute arthritis
algorithm, 1920f
mast cell involvement, 240
mast cell role, 241f
- Acute bacterial arthritis
clinical features, 1772
designation, 1803
monoarticular characteristic, 1804
- Acute brachial neuropathy, 660
- Acute calcific periarthritis, 581
- Acute cutaneous lupus erythematosus (ACLE), 1272, 1275-1277
generalized form, 1273
lesions, typification, 603
malar rash/butterfly rash, 1270f
- Acute digital ischemia, drug treatment, 1376f
- Acute gouty arthritis, 1556-1557, 1566-1567
classification criteria, 1557t
colchicine/NSAIDs, usage, 1572
- Acute gouty attack, 1545-1550
- Acute gouty response, propagation, 1549f
- Acute HCV infection, benign characteristic, 1871
- Acute hemarthrosis, 1915
distribution, 1916f
- Acute hemorrhagic edema, 609
- Acute inflammation, 414-420
cytokines, 373

- Acute inflammatory arthritis (development), tamoxifen (impact), 1946
- Acute inflammatory symptoms (management), interventions (usage), 534
- Acute knee monoarthritis, presentation, 583
- Acute leukemia, study, 1946
- Acute low back pain, 676-678
activities, 676
pharmacologic therapy, usage, 676
- Acute lymphocytic leukemia (ALL), 1753-1754
- Acute macrotrauma, impact, 726
- Acute malar rash, butterfly distribution, 603f
- Acute monoarthritis, 580-581
acute calcific peri-arthritis, 581
arthrography, usage, 578
blood, 577-578
bone biopsy, 579-580
calcium phosphate crystal arthritis, 581
cholesterol crystal arthritis, 581
computed tomography (CT), usage, 578
crystal arthritis, 581
diagnoses, 580-582
examination, 577
gout, 581
history, 577
imaging studies, 578
internal derangement, 582
investigations, 577-580
Lyme disease, 582
MRI, usage, 578
musculoskeletal ultrasound, usage, 578
plain radiographs, usage, 578
plant thorn synovitis, 582
polyarthritis presentation, 582-583
radionucleotide scans, usage, 578
reactive arthritis, 581-582
septic arthritis (bacterial), 580-581
synovial biopsy, 579-580
synovial fluid, 578-579
trauma, 582
urine, 578
- Acute monoarticular arthritis, pseudogout (impact), 1584
- Acute myeloid leukemia (AML), risk, 162
- Acute myocardial infarction, population-based study, 507
- Acute pain, causes, 578t
- Acute phase phenomena, 820t
- Acute phase proteins, 822
hepatic stimulation, induction, 819
inflammation markers, 823t
plasma acute phase protein, changes, 820f
- Acute phase reactants, 591
adult-onset Still's disease, 824-825
ankylosing spondylitis, 825
giant cell arteritis (GCA), 824
osteoarthritis, 825
polymyalgia rheumatica, 824
systemic lupus erythematosus, 824
usage, 823-825
- Acute phase response, 819-823
adult-onset Still's disease, 824-825
C-reactive protein, 820-822
cytokines, 823
erythrocyte sedimentation rate, 819-820
rheumatoid arthritis, 823-824
serum amyloid A, 822
systemic lupus erythematosus, 824
- Acute pseudogout
association, 1584
attacks, 1584
- Acute renal failure, NSAID (relationship), 885
- Acute rheumatic fever (ARF)
abdominal pain, 1883
antibiotic prophylaxis, 1885
arthritis, 1881
cardiac tissues, host immunoglobulin/complement (deposition), 1879
carditis, 1882
cell wall mucopeptides, relationship, 1877
chorea, 1883
clinical course, 1884-1885
clinical features, 1880-1884
clinical manifestation, autoimmune antibodies (presence), 1879
diagnosis, revised Jones criteria, 1881t

 cells, 62-64
 compression vulnerability, increase, 1696
 connective tissue, 61
 death (osteonecrosis), 1692
 densitometry
 bone mass, quantitative measure, 1665
 indications, 1665t
 Scientific Advisory Board of the National Osteoporosis Foundation guidelines, 1665
 density, 1120-1121
 assessment, 1664-1667
 characteristics, 840
 destruction, 1101-1105
 regulation, 1104-1105
 destructive pathways, dietary components (effects), 1048t
 disease, occurrence, 1393-1394
 edema
 lesions, 854
 T1-weighted MRI, 1239f
 erosion
 spondyloarthritis, 842f
 U.S. pathology definition, 858
 external shape, 61
 formation, vasoactive intestinal peptide/ CGRP support, 425
 formation/description, coupling, 64-65
 histopathology, 1730
 HIV-associated bone/joint disease, 1851-1854
 homeostasis, immune factors (involvement), 1697
 impaction grafting, 1704-1705
 invasion, 1961
 lesions, hematogenous implantation, 1832
 mass
 dual-energy x-ray absorptiometry (DEXA), usage, 1665
 quantitative measure, 1665
 matrix, 61
 removal, 64f
 menopausal bone loss, pathophysiology, 1661-1664
 metabolism, quantitative determination, 1640
 mineralization, occurrence, 1673-1674
 NSAIDs, impact, 887
 Paget's disease, 1674-1676
 treatment, indications, 1675t
 postdevelopmental maintenance/repair, 64
 primary lymphoma, 1945
 primary malignancies, 1945
 profile, osteophytes (presence), 862-863
 regeneration, 94
 remodeling, 65
 cycle, 1662f
 mast cells, implication, 239
 process, 64
 psoriatic arthritis, relationship, 1244
 sequence, 64f
 systemic control, neuroendocrine mechanisms (impact), 65-66
 resorption, 112
 sensitive indicators, 1666
 resorption (increase), PGE₂ (stimulation), 345
 scan/scanning
 display, 692f
 radiotracer increase, 697f
 usage, 668
 stabilizing bridge, ligaments (provision), 12

Bones (Continued)

structure/composition, 61-66
 surface erosion, 831
 synovial lesion invasion, 766f
 transverse displacement, 87f
 tumors, radiographic features, 1945
 turnover, biochemical marker development, 1666
 turnover, markers, 1666
 data, derivation, 1666
 types, 61
 Bone-specific alkaline phosphatase (BSAP), elevation, 1675
 Bony anatomy, detail (requirement), 709
 Bony erosions, 1210
 Bony thickening, formation, 1695
 Bony tophi, radiographs, 1560f
Borago officinalis (borage) seeds, oil extraction, 354-355
Borrelia burgdorferi, 1332
 antibodies, detection, 1822
 B cell/T cell responses, 1820
 erythema migrans (EM), association), 611
 genome, analysis, 1816
 IIM trigger, 1406
 immune response, 1816-1817
 infection, 226-227, 582
 impact, 1816-1817
 invasion, 1816
 larvae, impact, 1816
 Boston OA Knee Study (BOKS), 1593-1594
 Botanicals, salicylates (presence), 871-872
 Bouchard's nodes, 567
 presence, 535
 Boundary lubrication, 27
 Boutonniere deformity, finger description, 567
 Bovine serum albumin (BSA), 336
 Brachial neuritis, 660
 Bradykinin, pain sensitivity (increase), 345
 Brain biopsy, 1520-1521
 Brain habituation, reduction, 744
 Brain-specific angiogenesis inhibitor 1 (BAI1), 390
 BRCA1 C-terminus (BRCT) domains, study, 318
 Breastfeeding
 nursing, permission, 1321
 tocilizumab, 974
 tumor necrosis factor (TNF), 965
 Breast milk
 AZA transfer, 552
 CYC transfer, 553
 hydrochloroquine, impact, 551
 IgG transfer, 553
 British Orthopaedic Association, joint swelling management guidelines, 579f
 British Society for Rheumatology, joint swelling management guidelines, 579f
 Broken teeth, xerostomia (impact), 1187-1188
 Bronchiolitis, 1124
 Bronchiolitis obliterans organizing pneumonia (BOOP), 1275
 Bronchoalveolar lavage (BAL), 1182-1183
 inflammatory cell level, 1385
 usage, 1275
 Bronchogenic carcinoma, non-nodular cortical bone uptake (increase), 1687f
 Bronze diabetes, 1907
Brucella abortus microorganism, 186
 Brucella arthritis, 1261-1262
 cause, 1262
 clinical features, 1262
 diagnosis, 1262
 epidemiology, 1261-1262

Brucella arthritis (Continued)

 blockade, 978
 impact, 362
 induction, 957
 injection, 415
 production, n-3 fatty acids (effect), 1045
 Proinflammatory HDL (piHDL), presence, 509
 Proinflammatory intracellular signaling pathways, 418
 Proinflammatory macrophages, 1088-1092
 Proinflammatory mediators, neutrophil
 production, 160-162
 Prokaryotic DNA, detection, 1065
 Proliferating cell nuclear antigen (PCNA), chromatin-associated autoantigen, 796
 Proliferative bone diseases, 1681t
 Proliferative cartilage layer, 61
 Proliferative lupus nephritis (PLN)
 AZA, usage, 1322
 biopsy, 1306
 cyclosporin A (CsA), usage, 1311
 maintenance regimens, 1309
 MMF, usage, 1322
 RCT, meta-analyses, 1316
 treatment, recommendation, 1317f
 Proliferative synovitis, hemophilia, 1918f
 Proline and arginine-rich end leucine-rich repeat protein (PRELP), 37
 presence, 11
 Proline-serine-threonine phosphatase interacting protein 1 (PSTPIP1), 1612
 pyrin, interactions, 1612
 Prolyl-3-hydroxylase 1 (P3H1), 1728-1729
 Pro-matrix metalloproteinases (ProMMPs)
 activators, 109t
 molecules, short-lived intermediate (generation), 108
 ProMMP-2, uniqueness, 108-109
 ProMMP-7, pericellular activation, 109-110
 PROMPT trial, 1145
 Prophylactic method, absence, 457
Propionibacterium acnes
 cultures, 662
 infection, 674
 Proprioception, sensation, 634
 Prospective cohort study, 435
 advantage, 435
 disadvantage, 435
 Prostacyclin (PGI₁), 340, 345
 discovery, 345
 generation, 345
 intravascular infusion, 345
 Prostacyclin (PGI₂), vascular production (increase), 1046
 Prostaglandin E₁ (PGE₁), orphan status, 354
 Prostaglandin E₂ (PGE₂), 62
 abundance, 873-874
 protection, 351
 usage, 52
 Prostaglandin G/H synthase (PGHS), 871
 Prostaglandin I₂, contribution, 1084
 Prostaglandin (PG) production, 345, 873-874
 blockage, 871
 strategy, 890b
 COX-1/COX-2, impact, 884
 inhibition, 877
 Prostaglandins (PGs), 340
 action, 873-874
 mediation, G protein-coupled receptors (usage), 874
 arachidonate metabolites, 1083-1084
 autocrine/paracrine mediators, 873
 biosynthesis, inhibition, 872
 COX pathway product, 344-345
 cross-signaling, 418
 impact, 1630-1631
 joint destruction mediation, 920
 receptors, 351-352
 role, 353-354
 stability, 1083-1084
 structure, 344-345
 synthases, 344
 synthesis (increase), LPS (impact), 872
 Prostaglandin J₂ (PGJ₂), usage, 52-53
 Prostanoid acid skeleton, 344-345
 Prostanoids
 biology, history, 871-872
 biosynthesis, 342
 impact, 887
 Prosthetic disk, usage, 679
 Prosthetic joint infections, 1809-1811
 division, 1781
 inflammatory blood laboratory markers, sensitivity/specificity, 1810
 joints, aspiration, 1810
 medical therapy, 1810
 pain, symptom, 1810
 prevention, 1811
 treatment, complexity, 1810-1811
 Prosthetic joints
 bacterial infection, pathogenesis, 1782
 late infection, incidence, 1782
 Protease-mediated microbial destruction, 159-160
 Proteases, 363
 activity, inhibitors, 1104
 granule contents, 236
 release, 1082
 usage, 363
 Proteasome-ubiquitin pathway, protein degradation, 1434f
 Protein
 citrullination, 807f
 structural/functional implications, 810
 concentration, ratio, 15f
 consumption, impact, 1048
 modification, 1069, 1434
 synovial fluid concentrations, 15
 Protein A, superantigen (designation), 1773-1774
 Proteinases, 110-113
 activity, regulation, 106-110
 gene expression, 106-108
 impact, 1629-1630
 involvement, 98t
 production, 111
 Proteinase-3 (PR3), 1481
 PR3-, detection, 1490-1491
 Protein disulfide-isomerase, 807-808
 Protein kinase A (PKA), activation, 156
 Protein kinase B, 389
 Protein kinase C (PKC)
 DAG activator, 341-342
 kinase family, 156-157
 Protein kinase Cz (PKCz), activation, 55
 Protein kinase RNA-like ER kinase (PERK), 387-388
 Protein tyrosine kinases (PTKs), 179
 activation, 179-180
 families, involvement, 179-180
 Protein tyrosine phosphatases (PTPs), 202
 Protein tyrosine phosphatase-22 (PTP-22), 1059-1060
 associations, 1062
 LYP encoding, 1484-1485
 polymorphisms, 1062
 risk variant, studies, 1278
 Proteinuria, preeclampsia syndrome, 541-542
 Proteinuric flares, 1295
 Proteoglycan-induced arthritis (PGIA), 282-283
 Proteoglycan markers, 482
 Proteoglycans (PRGs), 11
 aggrecan-induced arthritis, 407
 aggregate, formation, 37
 decorin, 34
 degradation, MMP (impact), 49
 encoding, 3-4
 granule contents, 236
 molecules, accumulation, 1346
 synthesis, TGF stimulation, 46
 Proteoglycan 4 (PRG4), product, 27
 Proteolipid protein (PLP), impact, 292
 Proteomics, 485-486
 Proteasomal components, autoimmunity, 1433
 Prothrombin (G20210A), presence, 1336
 Proton magnetic resonance spectroscopy, usage, 743-744
 Proton pump inhibitor (PPI)
 naproxen (combination), 880
 usage, 883-884
 Proto-oncogene, *Bcl-2* translocation, 520
 Provocative tests, 635
 Proximal-distal outgrowth (direction), AER (impact), 5
 Proximal femur, bone scan (radiotracer increase), 697f
 Paget's disease, 1674f
 Proximal interphalangeal (PIP) joints
 articular cartilage, destruction, 111f
 cock-up toe deformities, 1118-1119
 contractures, 1392
 evaluation, 1163
 hyperextension, 1114f
 hypertrophic osteoarthritis, 1684f
 polyarticular arthritis, 1113f

ligand lipopolysaccharide, administration, 1088
transmembrane polypeptide, presence, 261f
- Toll-like receptor 7 (TLR7)
copy number variation, 1772
overexpression, 286-287
single-stranded RNA, 261
- Toll-like receptor 9 (TLR9)
initiations, 1065
sensing ability, 286-287
unmethylated bacterial DNA, 261
- Toluidine blue, usage, 33-34
- Tongue, AL amyloidosis, 1893f
- Tophaceous deposits, formation rate, 1558
- Tophaceous gout, 1550
consequence, 1558
images, 837f
radiographs, 1559f
- Tophus (tophi)
Achilles tendons, 1559f
appearance, 837
bony tophi, radiographs, 1560f
composition, MSU crystals (impact), 1550
fifth digit, tophus, 1559f
impact, 1560
importance, 1550
occurrence, 1558-1560
photographic/radiographic evidence, 1565f
urate crystals, appearance, 756f
- Topical agents, usage, 1649-1650
- Topical NSAID formulations, development, 880
- Topical NSAID preparations, usage, 1649-1650
- Topical therapy skin disease, systemic antimalarials (usage), 1315
- Topoisomerase I (Scl-70), 518-519
- Torque (kinetics), 82-83
creation, 83f
- Torticollis, 633
- Total ankle arthroplasty, anteroposterior radiograph, 706f
- Total hemolytic complement (THC) assay, 332
- Total hip arthroplasty, 1706
- Total hip replacement, tuberculous arthritis, 1833f
- Total joint arthroplasty (TJA), 1038
in-depth interviews, 1038
- Total joint movement, analysis, 82
- Total joint replacement, 1921
time, 1642
- Total leukocytes, excess, 172
- Total lung capacity, depression, 1384-1385
- Total Sharp score (TSS)
change, 1153
data, 1152-1153
radiographic progression, 1152
- Toxicity/adverse events, 465
- Toxic nodules, 1663
- Toxic shock syndrome toxin (TSST), stimulation, 187-188
- Toxic shock syndrome toxin-1 (TSST-1), 1803-1804
- Toxoplasma gondii* parasite, IIM trigger, 1406
- Trabecular bone, composition, 61
- TRACE-RA (Trial of Atorvastatin in the Primary Prevention of Cardiovascular Endpoints in Rheumatoid Arthritis), 510
- TRAIL (Tumor Necrosis Factor-Alpha-Related Apoptosis-Inducing Ligand)
adenoviral transfer, 1097-1098
cell surface inhibitory molecule, 288
- Training stimulus, duration, 76
- Tramadol, 1019-1020
bioavailability, 1019-1020
physical dependence/abuse, 1020
usage, 1651
- Transcellular migration, 153
- Transcription factors, 1094-1096
Hox encoding, 5
impact, 39
- Transcriptomics, 485-486
- Transcutaneous electrical nerve stimulation (TENS), 1648
benefits, 534-535
usage, 678
- Transdermal fentanyl, usage, 1651
- Transforming growth factor- β (TGF- β), 46, 227-228
activity, blocking, 1359
binding, 37
BMP, structural similarities, 62
cellular signaling, 1359
examples, 3f
expression, induction, 391
fibrosis, molecular determinants, 1359
IL-6/IL-23, addition, 277
impact, 362, 1071
injection, impact, 57
isoforms, 249
mediation, 119
medication, SMAD pathway (impact), 48
naming, 46
neutrophil chemoattractant, 161
signal transduction, 47-48
signaling, 91
source, platelets (impact), 245
superfamily, 46-47
members, role, 91
synovial fluid concentrations, 1198-1199
usage, 1092-1093
- Transforming growth factor- β activating kinase (TAK1), 1359
- Transgenic mice
model, syngenic mouse MHC class I overexpression, 1410
tissue/cell lineage-specific overexpression, 369-370
- Transgenic T cell receptor, 282
- Transglutaminase (TG) activity, mediation, 1582
- Transitional B cells, 197
B cell survival dependence, 197
- Transitional cells, 197
B cell subpopulation, 197
- Transmembrane activator and calcium-modulating cyclophilin ligand interactor (TACI), 1313
- Transmembrane dystroglycan-sarcoglycan complex, C-terminus (binding), 73
- Transmembrane PRRs, activating signals, 284
- Transmission disequilibrium test (TDT), 309
- Transmural eosinophilic infiltrate, 1490f

- Transplant rejection, antimetabolites (usage), 521
- Transporter associated with antigen processing (TAP), peptide transportation, 125
- Transrepression, 898-899
- Transthoracic echocardiogram (TTE)
murmur evaluation, 1275
usage, 1389
- Transthyretin (TTR), 822
amyloidosis, association, 1890
- Transthyretin amyloidosis (ATTR), 1890, 1895-1896
- Trauma-related osteonecrosis, anatomic considerations, 1695
- Traumatic arthritis
characterization, 725
TMJ, 725
treatment, 725
- Treatment of Early Aggressive RA (TEAR)
trial, 936, 1145-1148
clinical findings, 1147-1148
conclusions, 1148-1149
design, 1150
radiographic improvement/progression, 1149f
treatment groups, schematic, 1148f
treatment results, 1148f
- Treatments
dollar costs, 465
effectiveness, evidence, 436-437
escalation, schematic, 1139f
- Trendelenburg lurch, 694
- Trendelenburg test, usage, 569
- Trial analysis, 457-460
hypothesis testing, 457-458
limitation, 458
problems, 458-459
selection processes, net result, 459
- Trial design, 452-457
considerations, 453
effect, measurement, 455-456
follow-up considerations, 454
outcome variables, choice, 455
randomized clinical trials, 452-455
subject selection, 453-454
- Trial of Atorvastatin in the Primary Prevention of Cardiovascular Endpoints in Rheumatoid Arthritis (TRACE-RA), 510
- Trial result, interpretation, 456f
- Triamcinolone hexacetonide (THA), usage, 1754-1755
- Triangular fibrocartilage complex (TFCC), 714
ancillary studies, 715
injury, 714-715
tears, 714
- Trichrome staining, 1416f
- Tricuspid annular plane systolic excursion (TAPSE), 1388
- Tricuspid gradient (TG), usage, 1386-1387
- Tricuspid valve insufficiency, 1731-1732
- Tricyclic antidepressants (TCAs), 1023-1024
drug interactions, 1026t
pharmacodynamics, 1025t
side effects, 1024
- Trigger fingers, 566, 717, 1930
injection technique, 717f
location, 717
- Triggering receptor expressed on myeloid cells (TREM) 2, 63-64
- Trigger points
palpation, tenderness (presence), 642f
therapy, benefits, 534-535
- Trimethoprim/sulfamethoxazole (TMP/SMX), treatment, 1847
- Triple-helical collagen
cleavage, collagenases (impact), 1624
type II, B-cell epitope identification, 809
- Triple helical glycine residue, 1726
- Tripterygium wilfordii* active ingredient (Celastrol), 365
- Trochanteric bursitis, 570
lateral thigh pain, 693
- Trochanteric pain syndrome (bursitis)
arthrocentesis, 782
injection, 782f
- Tropheryma whippelii* infection, 582-583
- True ankle, hinged joint, 574
- Truthful, term (usage), 455
- Trypanosoma cruzi* parasite, IIM trigger, 1406
- Tryptatin, Kunitz-type inhibitor, 104-105
- Tryptase, 98
granule protein, 236
- Tryptophanyl-t-RNA-synthetase, expression, 128
- Tsk1/+ mouse, characterization, 1350
- Tsk2 mouse, scleroderma animal model, 1350
- T-tropic strain, 1856
- T tubular system, 63
- T-tubules, cutting, 63f
- Tuberculin skin test (TST)
recommendation, 1322-1323
usage, 1835
- Tuberculosis (TB)
advanced diagnostic testing, 1835-1836
bone biopsy specimens, mycobacterial colony counts, 1831
culture, 1835
diagnosis, 1835-1836
drug-resistant TB, incidence (increase), 1836
emergence, 1833-1834
false-positive results, 1835
imaging, 1835
infection, 1322-1323
interferon- γ release assays (IGRAs), 1835-1836
M. tuberculosis infection, treatment, 1836
nucleic acid amplification, 1836
open biopsy technique, 1833
PPD skin test, 1835
pyrazinamide, impact, 1834
rarity, 1829
reactivation
occurrence, 1834
risk, reduction, 1834
setting, reactive immunologic phenomenon, 1834
spondylitis, 1831f
surgical intervention, 1836
therapy, approach, 1836
treatment, 1836
impact, 1834
- Tuberculous arthritis
diagnosis, 1832-1833
knees, 1833f
total hip replacement, relationship, 1833f
- Tuberculous joint involvement, 1832
- Tuberculous osteomyelitis, 1832
occurrence, 1832
